The fact that both charge transfer bands ( $485-640\text{ m}\mu$ ) of the metmyochromogen disappear with radiation gives additional evidence supporting the conversion of the high-spin ferric to the low-spin ferrous form<sup>8</sup>. It has been

$5 \times 10^5$	424	422	426	429

generally accepted that the iron of the porphyrins in cooked meats is reduced by ionizing radiation<sup>1</sup>. If reduction was the only effect of radiation on iron, then the high-spin ferric porphyrin compound of cooked meats would have been converted to a high-spin ferrous compound. In this case, the spectrum of such a compound would have shown only one band of medium intensity, located at 545 mμ, and not a two-banded spectrum<sup>2,3,4</sup>.

The spectra of the irradiated cooked meats show that during radiation the spin state of the iron is altered while iron is being reduced. Since the spin state of a metal ion in a co-ordination complex depends on the electro-negativity of the ligands, then it follows that replacement of the ligands of the iron during radiation must precede any changes in spin state. It is, therefore, evident from the presented spectra that the electro-negative ligands of the iron of the high-spin metmyochromogen of the cooked meats are gradually replaced during radiation by electro-positive ligands. Then the latter induce the change in the spin state of the iron.

In view of the foregoing results, the mechanism of colour conversion of the cooked meats by ionizing radiations may be visualized as follows: at low radiation doses, at least one of the ligands of the iron in the metmyochromogen, and most probably water, is dissociated from the complex and is replaced by a less electro-negative group present in the medium. The new ligand is then responsible for the gradual change in the spin state of the iron, from the high- to the low-spin form. At the same time, some of the iron is being reduced. At radiation doses above  $5 \times 10^5$  rads, the dissociation of both ligands of the iron increases, together with their replacement by electro-

positive ones, while more iron is reduced. Thus, at  $5 \times 10^5$  rads, most of the iron is converted to the low-spin ferrous form.

It is thought, therefore, that the compound responsible for the colour of the irradiated cooked meats and at radiation doses up to  $5 \times 10^5$  rads is a mixture of high-spin ferric, high-spin ferrous and low-spin ferric porphyrin co-ordination compounds. At radiation doses above  $5 \times 10^5$  rads, the mixture consists mostly of a low-spin ferrous and a low-spin ferric porphyrin. The contribution to the mixture of the low-spin ferrous form increases with the radiation dose.

Because of the recent interest in radiation pasteurization, it has to be pointed out that cooked meats, subjected to low radiation doses, would be unstable from the lipid oxidation point of view, since most of the pigment would be in the high-spin form<sup>11</sup>. Such oxidative changes, however, may be effectively prevented by the use of suitable antioxidants<sup>12</sup>.

## ABSENCE OF ANTIBODY PRODUCTION IN THE BURSA OF FABRICIUS

By DR. PETER B. DENT\* and PROF. ROBERT A. GOOD†

Pediatric Research Laboratories, Variety Club Heart Hospital, University of Minnesota, Minneapolis

THE importance of the bursa of Fabricius in the development of humoral immunity in the chicken has become well established since the finding that early bursectomy prevents the production of antibody to a bacterial antigen<sup>1,2</sup>. Furthermore, it has recently been clearly demonstrated that complete bursectomy in the neonatal period, coupled with sub-lethal irradiation, results in both permanent agammaglobulinaemia and absence of germinal follicles and plasma cells from the spleen<sup>3</sup>. However, although the vital role of the bursa in the development of the immunoglobulin-producing system has been established, the precise mechanism by which it exerts its influence has not been fully elucidated and is now the subject of much investigation.

An analogous situation existed with regard to the function of the thymus after it had been demonstrated to be essential for the development of cellular immunity and to a lesser degree for the development of humoral immunity. However, it soon became apparent that the thymus exerts its function in at least two ways. The work of Noessl<sup>4</sup> and Sainte-Marie and Leblond<sup>5</sup> has shown clearly that the thymus can act by distributing lymphoid cells to the peripheral lymphoid organs. The chromosome and immunological marker investigations of Miller<sup>6</sup> and of Dalmaso *et al.*<sup>7</sup>, followed by the diffusion chamber experiments of Levey *et al.*<sup>8</sup> and Osoba and Miller<sup>9</sup>, have established a humoral function for the thymus in mice, and since then evidence for a humoral function in rats has been presented by Aisenberg and Wilkes<sup>10</sup> and MacGillivray *et al.*<sup>11</sup> and in the hamster by Wong *et al.*<sup>12</sup>.

Recently, St. Pierre and Ackerman<sup>13</sup> and Janakovic and Leskowitz<sup>14</sup> have demonstrated that the bursa exerts its effects at least in part by a humoral action. Peterson *et al.*<sup>15</sup> have shown that the bursa of Fabricius is essential to development of lymphoid malignancy in the chicken and more recent investigations indicate that this malignant development is probably dependent on the humoral influence of the bursa<sup>16</sup>. The question of whether the bursa distributes a population of cells with a particular developmental potential remains unanswered.

In other investigations of the role of the thymus in immune mechanisms, Billingham *et al.*<sup>17</sup> and Mathé *et al.*<sup>18</sup> have shown that thymic cell suspensions can exert graft-versus-host reactivity although much less effectively than spleen cell suspensions. It is also known that the reactivity of these cells can be greatly increased by prior immunization *in vivo*<sup>19</sup>. It is thus apparent that the thymus can take part in the expression of cellular immunity as well as being essential for its development. Evidence that bursal cells produce specific antibody *in situ*, as well as being responsible for the development of immunoglobulin production, has been scanty and inconclusive<sup>20</sup>. As part of our investigations of the role of the bursa of Fabricius in humoral immunity, we have found that the bursal cells do not produce specific haemolysins or haemagglutinins to sheep red blood cells.

The technique of Jerne<sup>21</sup> for the detection of haemolysin production by single cells in agar gel and the method described by Zaalberg<sup>22</sup> for the detection of haemagglutinin production by single cells were found to be suitable for this investigation. The former method was used as described by Jerne except that 2 ml. of a 1:1 dilution of fresh-frozen whole chicken plasma was put on

to the plates for 10 min at  $37^{\circ}\text{C}$  prior to the addition of guinea-pig complement. This was necessary because avian antibody requires the species-specific first component of complement in complement-dependent reactions<sup>14</sup>. For the detection of haemagglutinin-producing cells, approximately  $10^7$  cells were added to a 1 per cent suspension of washed sheep red blood cells in Eagle's basal medium in screw-top 10-ml. test-tubes. These were incubated in a shaker water bath at  $37^{\circ}\text{C}$  for 2 h. The cells producing haemagglutinin were identified by the adherence of sheep red blood cells to them, and these clusters were readily counted (Fig. 1) in a haemocytometer under 100 times magnification.

Five week-old White Leghorn chickens obtained from a commercial hatchery were used in this work. They were immunized three times at three-day intervals with 0.2 ml. of washed packed sheep red blood cells intravenously. Three days after the last injection they were bled and the spleen, bursa and two thymic lobes were removed. A single cell suspension in Eagle's basal medium was made by mincing the tissue with fine scissors and pressing the fragments against the walls of a Potter-Elvehjem homogenizer with the handle of the pestle. The pestle was then placed into the homogenizer and allowed to drop to the bottom by the force of gravity. The overlying fluid was removed and left to stand in the cold for 15 min to allow the larger fragments to sediment out. The cell suspension was then decanted and centrifuged for 10 min at 1,000 r.p.m. at  $4^{\circ}\text{C}$ . The sedimented cells were resuspended in Eagle's medium to give the desired concentration. Viability was determined by the trypan blue dye exclusion method, and cell counts were performed using 2 per cent acetic acid as diluent. As chicken red blood cells are nucleated and are not lysed by acetic acid, the percentage of red blood cells in the spleen cell suspension was determined by doing a differential count and the total cell count was correspondingly adjusted to exclude red blood cells. There were negligible numbers of red blood cells in the thymus and bursa cell suspensions.

The results (Tables 1 and 2) show very clearly that the bursa and thymus cell suspensions contain insignificant numbers of cells producing either haemolysin or haemagglutinin against sheep red blood cells. The few antibody-producing cells found in these organs could be the result of contamination of the organ cell suspensions by antibody-producing cells from the peripheral blood.

The difference between the number of cells producing haemolysin and the number producing haemagglutinin is in accord with Zaalberg's observations in the mouse. Although we realize that the rate of haemagglutinin synthesis may be greater than that of haemolysin synthesis by the individual cells, we feel that the 1,000-fold differences we observed in the number of antibody-producing cells detected by these methods may have been exaggerated for the following reasons. It may be that the figures obtained in the Zaalberg assay are too high, because in some of these clusters one is unable to see the antibody-producing cell (Fig. 2), which, indeed, may not be present—the cells agglutinating simply as a result of liberation of the agglutinin into the medium. On the other hand, the results of the Jerne assay may be too low. The plaques formed in the agar gel by haemolysin-producing cells were quite small and had to be counted under the dissecting microscope at 10 times magnification. We noted at 30 times magnification many very small areas of incomplete haemolysis which may represent cells producing insufficient antibody to form a distinct plaque (Fig. 3) or sub-cellular

particles which have recently been shown to be capable of plaque formation<sup>15</sup>. The value of these techniques in qualitative and semi-quantitative assessment of antibody production by single cells is unquestionable. However, it seems doubtful if their accuracy is adequate for precisely quantitative investigations.

A previous examination of the production of specific antibody by the bursa was made using fluorescent antibody techniques, and it was suggested that bursal cells

Fig. 3. 50 times magnification of a typical haemolytic plaque and, below it, an area of incomplete haemolysis

did produce specific antibody after immunization with bovine  $\gamma$ -globulin<sup>10</sup>. The validity of this work has been questioned because of the failure to show specificity of the staining. We have shown conclusively that the bursa does not produce antibody to an antigen which elicits a strong antibody response in the cells of the spleen. If it is true that the bursal cells do not produce specific antibody, it now becomes of great importance to discover whether they produce  $\gamma$ -globulin, for if this were so it would provide indirect evidence for the existence of  $\gamma$ -globulin without antibody specificity and would have far-reaching implications regarding the mechanisms of antibody formation<sup>11</sup>. Further investigations along this line are in progress.

The concept of central lymphoid tissues, the prime function of which is to ensure the normal development of immune mechanisms which are, in turn, expressed by the peripheral lymphoid tissues, is a useful one. The notion of the thymus as a source of the lymphocytes in the peripheral lymphoid tissues, originally proposed by Beard<sup>12</sup>, has been modified to take into account the recent developments in the field of immunobiology, particularly the emphasis on hormonal influences and on the analogous 'source tissue' functions of such tissues as the bursa of Fabricius. The experiments reported herein, demonstrating the lack of antibody-producing cells in the bursa of Fabricius, provide further evidence for the distinction between the central and peripheral lymphoid tissues.

## AN AUTOMATIC DYNAMIC SPECTRUM ANALYSER FOR TAPE-RECORDED SIGNALS

By DR. R. L. DOWDEN and M. W. EMERY

Department of Physics, University of Tasmania

A DYNAMIC spectrum analyser provides amplitude or intensity as a function of both frequency and time of transient signals such as music, speech, atmospheric 'whistlers', geomagnetic micropulsations, etc. Typically, for such phenomena, one requires a frequency

resolution  $\Delta f$  corresponding to 1 per cent or less of the frequency range of the phenomena and a time resolution limited only by the uncertainty relation  $\Delta f \cdot \Delta t \approx 1$ . Two types of analyser are commercially available. The first uses a bank of several hundred narrow band-pass

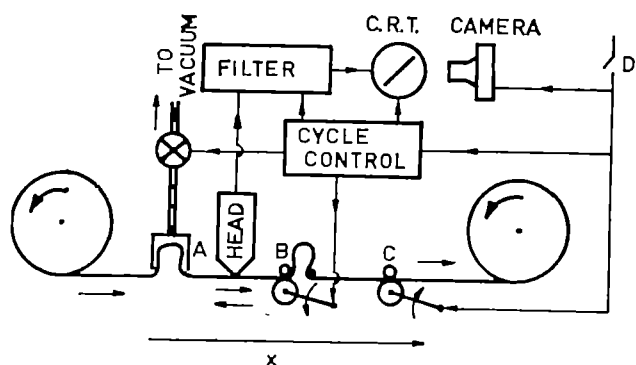

Fig. 1. The complete spectrum analyzer, showing details of the multiple pass system

Fig. 2. The locus of a point on the tape as it passes through a 16-pass system. The slopes correspond to the slow capstan, playback and flyback speeds. The  $s$  direction is as shown in Fig. 1

filters. This type has the advantage of 'real-time' analysis but is expensive and inflexible. The second type uses a single narrow band which is tuned (usually by a hetero-

dyne system) over the desired range. However, in order to obtain the maximum available time resolution the signal must be passed several hundred times through the filter. In fact, it is easily shown by the uncertainty principle that the number of passes required is about equal to the number of filters required in a filter bank analyser. Its advantages follow from the use of only one filter. Thus it is relatively inexpensive and highly flexible in that its frequency range and frequency resolution are easily adjusted manually or automatically to follow a pre-set programme. Its obvious disadvantage is related to the large number of passes. Even for high-speed replay, continuous analysis of long signals is very tedious.

Some ingenious methods (for example, ref. 1) have been devised to overcome this, even to the extent of providing 'real-time' analysis. However, in our case the phenomena are already recorded on tape. What we required was an

Fig. 3. A photograph of the tape deck showing the modifications. A, B, C and D correspond with the points so marked in Fig. 1. The filter and display are not shown

Fig. 4. Continuous spectrograms produced by the analyzer in Fig. 1. The upper one shows a very-low-frequency 'nose whistler' and the lower one a train of 'micropulsation whistlers' (both phenomena were recorded at Hobart)

analyser which would provide continuous analysis of any length of tape completely automatically. A long analysis time, provided the operator's time was not involved, was quite acceptable.

The principle of operation is illustrated in Fig. 1. Between *A* and *B* the tape travels at the normal playback speed (4.75 cm/sec) controlled by the capstan *B*, or very much faster in the reverse direction when vacuum is applied at *A* and the capstan *B* is disengaged. Thus the tape executes an oscillatory 'saw-tooth' motion past the pick-up head. The forward travel is determined by the programmed duration of a pass (since the speed is fixed). The extent of the 'flyback' is determined by the size of the loop at *B*. However, since part of this loop has been pulled out by the slow speed capstan *C* during a pass, the flyback travel is slightly less than the forward travel. Thus the sample of tape passed is changed slightly after each pass. It will be seen that the number of times a given point on the tape passes through the head is equal to the velocity ratio of capstans *B* and *C*. The position  $x$  of such a point as a function of time is shown in Fig. 2, for a capstan velocity ratio of sixteen. A photograph of the tape deck taken during operation is shown in Fig. 3.

A saw-tooth voltage synchronized to the tape motion controls the frequency of the filter and provides the frequency-time base trace for the display cathode ray tube. The detected output of the filter is applied to the cathode-ray tube as intensity modulation. The modulated trace is recorded on continuously moving film. Note, however, that since the analyser scans in both frequency and time, the trace must be inclined at a certain angle relative to the film direction in order to obtain orthogonal fre-

quency and time axes on the resulting spectrogram. The film speed is adjusted for slight overlap of successive traces. The frequency-time aspect ratio is then controlled by the slow capstan (*C*) speed. This is made adjustable so as to provide only the required aspect ratio (and time resolution) with a consequent saving in both film and analysis time.

Examples of dynamic spectrograms made by this analyser are shown in Fig. 4. When referred to the playback speed (4.75 cm/sec) the frequency range in each case was 0–10 kc/s, the filter band width (frequency resolution) 80 c/s, and aspect ratio about 10 kc/s = 1 sec. The real time or record speed values depend on the play-back/record speed ratio, which was very high for the long period phenomena. The capstan velocity ratio (or pass number) was 385 in each case, which was somewhat greater than necessary. Note that the analysis time is less than 'real-time' when the capstan velocity ratio is less than the play-back/record ratio. Note also that tape recordable phenomena in any frequency range can be analysed by suitable choice of the latter ratio.

The method described here provides automatic and continuous spectrum analysis in a relatively simple way. The instrument involved only minor alterations to a standard commercial tape recorder. In fact if the recycling programme is switched off and the slow capstan disengaged it will operate as a 'normal' tape recorder. As an additional refinement our slow capstan is engaged by a solenoid. Thus at any time during 'normal' operation for aural monitoring, analysis can be started immediately by pressing switch *D* shown in Figs. 1 and 3.

## MULTIPLE TRANSVERSE BREAKAGE OF THE FILAMENTOUS PARTICLES OF TURNIP-MOSAIC VIRUS BY ULTRASONIC VIBRATION

By DR. J. A. TOMLINSON and D. G. A. WALKER  
National Vegetable Research Station, Wellesbourne, Warwick

D. E. HUGHES  
Department of Microbiology, University College, Cardiff

AND

DR. D. H. WATSON

Medical Research Council Department of Virology and Bacteriology, University of Birmingham

ATTEMPTS have been made by some workers to use the Ouchterlony agar diffusion precipitin test<sup>1</sup> for serological work on rod and filamentous-shaped viruses. When the length of the virus was comparatively short, as in the case of tobacco mosaic<sup>2</sup> (300 mμ) and barley stripe mosaic virus<sup>3</sup> (126 mμ), successful results have been obtained; but viruses with long filamentous particles appear to diffuse so slowly that satisfactory precipitation lines are rarely formed. Thus Ford<sup>4</sup>, working with clover yellow mosaic virus (539 mμ), obtained sharp precipitation lines only after 1–2 weeks. Purcifull and Shepherd<sup>5</sup>, however, were able to make gel-diffusion tests with four filamentous viruses by chemical degradation of the rods into protein fragments using ethanolamine and carbonate buffers. In some instances, however, the chemical treatments produced several serologically active components resulting in two or more precipitation lines.

In the investigation recorded here the principle of producing small, faster-diffusing fragments of a long filamentous virus particle was also used; but the method chosen was to attempt to fracture the particles by ultrasonic treatment. The use of this method to disrupt the particles of tobacco mosaic virus has been discussed by Bawden<sup>6</sup>. An isolate of the turnip mosaic virus originally obtained from rhubarb (*Rheum rhabontium* L.) was used in the test reported here. It was cultured in the leaves of mustard (*Brassica juncea* Cass.) and infected leaves were homogenized at 2° C in 0.5 M sodium borate

buffer (pH 7.5) containing 0.1 per cent thioglycolic acid. The virus was afterwards purified from the filtered homogenate by the borate-butanol method of Tomlinson<sup>7</sup>. The preparations were infective at dilutions of 10<sup>-4</sup> and they contained filamentous particles, most of which were approximately 720 mμ in length. Rabbit antiserum of the virus, obtained by a series of intravenous injections with purified virus preparations, reacted positively in precipitin tube tests with purified virus diluted in normal saline (titre 1/1024). No comparable reactions were obtained between the virus preparations and normal serum or between the antiserum and clarified healthy mustard leaf sap.

A purified preparation of the virus was treated for various times in a 500-W, 19–25-kc/s M.S.E. ultrasonic cell disintegrator. 5.0 ml. of the preparation in 0.01 M borate buffer (pH 7.5) was placed in a thick-walled, round bottom glass tube (3.2 cm internal diameter) which was cooled in ice water. Using the method described by Hughes<sup>8</sup> a titanium probe (stepdown from 5.8 cm to 2.0 cm) was set with its tip just below the surface and driven at power setting 4, which is just above the cavitation threshold of 0.7 atm/cm<sup>2</sup> for 12 min. 0.5 ml. aliquots were removed from the solution after 1, 3, 6 and 12 min treatment and the remaining solution was treated for 2 min at power-level 6 which is just sufficient to avoid cavitation unloading.

Preparations of the virus before and after ultrasonic treatment were negatively stained with a 2 per cent (w/v)

neutralized solution of phosphotungstic acid and mounted on to 'Formvar' coated grids for examination with a Siemens Elmiskop I electron microscope. Electron micrographs showed that the untreated preparations contained the long, flexuous filaments of the virus (Fig. 1). Ultrasonically treated preparations, however, contained predominantly much shorter particles (Fig. 2). The normal length of the negatively stained particles before the ultrasonic treatment was 722 m $\mu$  and the arithmetical mean length of the treated particles was 121 m $\mu$ . The length distribution of the rod-shaped particles in the untreated and ultrasonically treated virus preparations is shown in Fig. 3. There was little or no aggregation of virus particles in any of the virus preparations examined and preliminary observations have suggested that more of the surface detail structure of the virus was visible after the ultrasonic treatment.

Agar diffusion tests were made in 9-cm glass Petri dishes in 0.75 per cent agar dissolved in 0.9 per cent sodium chloride and 0.04 per cent sodium azide. The antiserum and antigen wells removed from the agar were 5 mm in diameter and spaced 6 mm apart. The pattern of wells used in the tests consisted of a central well containing the antiserum diluted 1/10 in normal saline surrounded by 8 peripheral wells which were filled with the virus preparations. The dishes were incubated at 20° C in a moist chamber.

After 1-2 days single precipitation lines were formed near the antigen wells filled with virus preparations that had received ultrasonic treatment, the intensity of the lines increasing with increasing treatment. By contrast no precipitation line was formed near the wells filled with either the untreated virus preparation or clarified mustard

Fig. 1. Electron micrograph of an untreated, partially purified preparation of turnip mosaic virus showing the mainly long filamentous particles

Fig. 2. Electron micrograph of a partially purified preparation of turnip mosaic virus showing the short-lengthed broken virus fragments after ultrasonic treatment

Fig. 3. The length distribution of particles in a preparation of turnip mosaic virus (a) before and (b) after ultrasonic treatment

Fig. 4. 36-h agar-diffusion test against turnip mosaic virus antiserum (central well). 1-4, virus treated for 12 min (power 4) plus 2 min (power 6); 5-6, untreated virus; 7-8, clarified mustard sap.

sap. Fig. 4 illustrates the precipitation lines formed after 36 h using virus that had been treated for 12 min at power 4 plus 2 min at power 6. It was concluded that the ultrasonic treatment of the virus particles had produced virus fragments that were still serologically active and which had a rate of diffusion greater than that of the virus particles present in the untreated preparations.

Following this initial experiment the treatments were repeated on a fresh sample of purified virus preparation and the results obtained in the first experiment were confirmed.

It is not known which of the various sizes of particle produced by ultrasonic treatment constituted the principal antigenic component, as the lower limits of fragmentation were not determined. It was noted, however, that in addition to the clearly discernible virus fragments, the electron micrographs of the ultrasonically treated preparations showed a background matrix of smaller particles. These were difficult to resolve but some were roughly circular and of about the same diameter as the width of the intact virus. The particles of turnip mosaic virus may be similar to those of tobacco mosaic virus or beet yellow mosaic virus<sup>8</sup> and consist of hollow helices composed of protein sub-units. If so, the circular particles seen in

the electron micrographs may be composed of one or more of these helices. Some of the virus may have been broken into even smaller units. These and other aspects of the ultrasonic treatment are now under investigation.

## SPLEEN AND LYMPH NODE FRACTIONS WITH ANTIBODY ACTIVITY

By DR. F. I. TSUJI, D. L. DAVIS and D. H. DONALD

Veterans Administration Hospital and Department of Biophysics, University of Pittsburgh, Pennsylvania

**T**HERE is substantial evidence that ribosomal particles are connected with protein synthesis. According to this concept, an unstable fraction of ribonucleic acid (RNA), formed through a deoxyribonucleic acid (DNA)-dependent synthesis<sup>1</sup> and acting as a messenger<sup>2-4</sup>, provides the code for protein synthesis to occur on polyribosomal particles<sup>5-7</sup>. A schematic model of this process has been postulated<sup>8,9</sup>.

Despite what is known about the mechanism of protein synthesis, little is known concerning the molecular aspects of antibody synthesis. Uhr<sup>11</sup> has observed that antibody formation by lymph node fragments cultured *in vitro* is inhibited by actinomycin D. This result has been interpreted to mean that antibody synthesis is DNA-dependent. Owing to the general effects of actinomycin D on protein synthesis, it is still difficult to specify the steps involved in antibody synthesis. For example, we cannot say in what manner and at what point during synthesis immunological specificity is conferred on the antibody. Except in a broad sense, we also do not know the molecular role that the antigen takes. We are also uncertain as to whether a messenger RNA is produced that contains the information for carrying out a complete synthesis.

In order to gain an insight into the process, extracts of spleen and lymph node cells from normal and immunized rabbits were examined by differential and sucrose density gradient centrifugations. The antigen used was luciferase, a highly stable enzyme responsible for the blue luminescence of the marine ostracod crustacean, *Cypridina hilgendorfi*. The enzyme catalyzes the oxidation of luciferin (substrate) by molecular oxygen with the emission of a blue light. The activity of luciferase is inhibited by antibodies ( $\gamma$ -globulin fraction) produced against the enzyme. Properties of this luminescent reaction, including methods for isolating luciferin, for measuring light intensity, and for quantitating luciferase activity, have been described previously<sup>12,13</sup>. Luciferase was isolated by fractional precipitation with ammonium sulphate and acetone, followed by gradient elution chromatography on diethylaminoethyl cellulose<sup>14</sup>. Rabbits were immunized with luciferase dissolved in isotonic saline (3 mg/ml.) and clarified at 105,000g for 1 h in a Spinco model L ultracentrifuge before use. In all cases, centrifugation yielded virtually no sediment. Subcutaneous injections were given above each shoulder according to the following daily schedule: 1st and 2nd day, 1.5 mg; 3rd-5th day, 3 mg; 6th-15th day, 0 mg; 16th-19th day, 3 mg. On the 20th day, when the level of anti-luciferase activity in serum approached a maximum, the animal was anaesthetized with ether, bled by heart puncture (blood later used to prepare antiserum), and killed.

The organs were immediately weighed and placed in cold Ringer's solution, containing 0.0056 M glucose.

Unless otherwise specified, all subsequent manipulations were carried out between 0°-4° C. The organs were cut into small pieces with a pair of scissors, placed in 30 ml. of a solution containing 0.14 M NaCl, 0.005 M KCl, and 0.0015 M MgCl<sub>2</sub> (solution 1), and ground by hand in a loosely fitting Potter-Elvehjem grinder to obtain a single-cell suspension (Fraction 1). Fraction 1 was then centrifuged for 10 min at 11,000g in a Servall RC-2 refrigerated centrifuge, to yield a supernatant (Fraction 2) and precipitate. The precipitate was washed again in 30 ml. of solution 1 and centrifuged at 11,000g. The supernatant (Fraction 3) was decanted and the precipitate was suspended in 25 ml. of 0.88 M sucrose containing 0.01 M *tris* (hydroxymethyl) aminomethane hydrochloride buffer, pH 7.4, 0.01 M KCl, and 0.0015 M MgCl<sub>2</sub> (Fraction 4). Fraction 4 was exposed to ultrasound between 2°-4° C in a Raytheon 50-W, 9-ko/s magnetostriction oscillator, model S-102A. Sound was applied as follows: 3 min, 2 min off, and 3 min. Cellular disruption was verified by microscopic examination. The treated suspension (Fraction 5) was diluted with a solution containing 0.01 M *tris*-hydrochloride buffer, pH 7.4, 0.01 M KCl, and 0.0015 M MgCl<sub>2</sub> (solution 2) to give 0.25 M sucrose (Fraction 6, final volume 88 ml.). After centrifuging at 20,000g for 10 min, the supernatant (Fraction 7) was decanted and the precipitate was re-suspended in 7 ml. of solution 2 containing 0.25 M sucrose (Fraction 8). The latter suspension was centrifuged at 780g for 10 min to remove nuclei, cell debris and possibly unbroken cells (Fraction 8B). The resulting supernatant (Fraction 8A) was then ground by hand in a closely fitting Potter-Elvehjem grinder to give Fraction 8AA. Fraction 7 (88 ml.) was further centrifuged at 105,000g for 1 h to give a supernatant (Fraction 9) and a microsomal precipitate<sup>15</sup> which was suspended in 5 ml. of solution 2 containing 0.25 M sucrose (Fraction 10). All Fractions were immediately frozen and stored at -15° C.

The Fractions were analysed in linear sucrose gradients prepared from 15 and 30 per cent, w/w, sucrose solutions containing 0.01 M *tris*-hydrochloride buffer, pH 7.4, 0.01 M KCl, and 0.0015 M MgCl<sub>2</sub> (refs. 16 and 8). Gradients were prepared in Spinco SW 25 tubes, 34 ml. capacity. 1 ml. of the suspension was layered over the surface and run in triplicate at 55,000g for 2 h. The gradient tubes were then immersed in ice-water and a fine stainless-steel needle, controlled by a rack and pinion arrangement, was lowered to the bottom of each tube. Fifty-one equal fractions were collected using a finger pump and fraction collector. From this point on, all manipulations were carried out at room temperature. Any pellet remaining at the bottom was taken up for assay in 0.61 ml. of 0.25 M sucrose. Control experiments showed that even with a highly active antibody fraction at the top, the procedure

did not significantly contaminate the pellet. All gradient fractions were stored at  $-15^{\circ}\text{C}$  for approximately 1 week before assay.

The absorbancy of each fraction was read against water at 280 m $\mu$  (antiseraum fractions were additionally read at 280 m $\mu$ ) in a Beckman DU spectrophotometer equipped with a microcell attachment (Pyrocell Mfg. Co., Westwood, New Jersey). To determine the relative position of gradient fractions from run to run, the refractive indices of selected fractions were read in a single-drop Zeiss model A Abbe refractometer, in sodium light. Sucrose densities calculated from refractive indices of standard mixtures showed the gradient to be linear. The calculated density at the top was 1.0490 g sucrose/cm $^3$  and at the bottom 1.1370 g sucrose/cm $^3$ , both measured at  $20^{\circ}\text{C}$ . The antibody activity in the collected fractions was assayed as follows<sup>12</sup>: To 3 combined gradient fractions, a constant amount of luciferase was added and, after standing for 3 h at  $25^{\circ}\text{C}$ , a saturating concentration of luciferin was added. The initial light intensity, measured with a photomultiplier photometer, was directly proportional to the concentration of unneutralized luciferase present. This value divided by the mean value of all fractions with no apparent antibody activity gave the fraction of initial luciferase activity remaining. The working sensitivity of the method was  $10^{-6}$  of the luciferase concentration used for immunization, with a lower limit of  $10^{-8}$ . Based on the observation that one antibody molecule inactivates a catalytic site<sup>11</sup>, the antibody assay was of the same order of sensitivity. The presence of luciferase was roughly estimated by adding luciferin to 3 combined gradient fractions, as in antibody assay, and measuring the light intensity. Luciferase activity ranged between  $10^{-6}$  and  $10^{-8}$  of the concentration used for immunization.

Table 1. ANTIBODY ACTIVITY OF SPLEEN AND LYMPH NODE FRACTIONS (Expressed arbitrarily as the number of units of luciferase activity neutralized) (Rabbit No. 440)

Fraction No.	Total activity in fraction		Activity/g (wet wt) suspended material	
	Spleen	Lymph node	Spleen	Lymph node
1	84	104	42	116
2	60	92	—	—
3	0	7	—	—
4	40	60	24	118
5	61	92	87	180
6	50	170	—	—
7	28	123	—	—
8	14	17	18	72
9	26	76	—	—
10	6	11	9	28

Table 1 consists of a typical set of data from one of ten rabbits studied. The column at the left shows the total activity of each fraction. The activities of Fraction 1 and 2 may be attributed largely to material released during initial grinding and to residual antiserum. Fraction 3, being a wash, contained negligible activity or none, and additional washings did not release further activity. The activity of Fraction 4 was always relatively high, possibly due to activity associated with partially broken cells and to additional activity released on re-suspension in 0.88 M sucrose. A pronounced increase in activity occurred after exposure to sound, as seen in Fraction 5. Dilution of Fraction 5 by a factor of approximately 3.5 caused lymph node activity to be almost doubled and spleen activity to be moderately reduced. This relative increase in activity occurred with practically every rabbit studied, indicating further release or exposure of new activity. Of five rabbits examined, Fractions 8, 8A, 8AA and 8B all showed activity, the highest total activity being found in Fraction 8B. For both organs, the gradient patterns showed antibody activity near the top in Fraction 8A, but in the lower regions in several separate bands in Fraction 8AA. The sum of the activities of Fraction 9 and 10 was not always found to add up to Fraction 7. Preliminary observations have indicated that the loss of

activity came about from both storage at  $-15^{\circ}\text{C}$  and particle aggregation similar to that observed by Gull-ohriest and Bock<sup>13</sup> for ribonucleoprotein particles in 3-30 per cent sucrose.

The column on the right in Table 1 contains specific activities for which wet weights of suspended material were readily determinable. Wet weights were determined directly in polypropylene centrifuge tubes, after the tubes were decanted and wiped dry. Owing to the large volume of Fraction 7 and to the tube capacity being 8.3 ml. for the Spinco No. 50 rotor, Fraction 7 was divided into approximately 10 equal volumes for the centrifugation. The wet weight of Fraction 10 was obtained by summing the 10 wet weights (making due allowance for the aliquot removed for assay). Control experiments were run as follows: Fraction 5 was exposed to sound, but instead of being diluted to 88 ml., the suspension was centrifuged at 20,000g for 10 min to obtain Fraction 7 (supernatant). Fraction 7 was then centrifuged at 105,000g for 1 h and the pellet was weighed directly in the tube. The wet weights of 'Fraction 10' obtained for 3 different spleens and 3 sets of lymph nodes averaged 14 times smaller than those obtained by the foregoing method. The specific activities of Fraction 10 are therefore undoubtedly too low. They would become the highest, however, if multiplied by any factor greater than 7.

While it might seem attractive to attribute antibody activity to microsomal particles, the results recorded here do not justify such a conclusion. Owing to inhomogeneity of Fraction 10, it would be equally reasonable, for example, to attribute the activity to a particle involved in antibody storage. In order to obtain further understanding, sucrose density gradient analyses were carried out on antiserum and Fractions 2, 7, 9 and 10. Fig. 1 represents the gradient data on antiserum. For all figures the bottom of gradient is shown at the left; antibody activity is represented by a bar-graph (for 3 combined gradient fractions); and pres-

Fig 1 Sucrose density gradient pattern for antiserum, diluted 1:20 with solution 2, 1.0 ml. layered

ence of luciferase is indicated by a horizontal line (below antibody baseline). Fig. 1 shows absence of antibody activity from all fractions except near the top (Fractions 40-51). Luciferase activity was also absent and the pellet showed neither antibody nor luciferase activities. Because of similarities in the gradient patterns, only the spleen pattern for Fraction 2 is presented (Fig. 2). The absorbency curve for lymph node was similar to that of spleen, with a peak at fraction 44. With both organs, the highest antibody activity was found near the top of the gradient (fractions 46-48 and 49-51), being highest in fractions 49-51. Spleen showed some antibody activity in fractions 4-6, 7-9, and 10-12, but lymph node showed only slight activity in this area. Fractions 37-39 of lymph node also possessed additional activity, equal to about one-eighth the total activity in fractions 49-51. When tested with luciferin, luciferase activity was detected in spleen fractions 1-3, 4-6, 7-9, 40-42, 43-45, 46-48, and 49-51, and in lymph node fractions 4-6 and 7-9. Antibody and luciferase activities were absent from the pellets of both organs. A rather surprising finding was the detection of both antibody and luciferase activities in the same fractions, as seen in spleen fractions 4-6, 7-9, 46-48 and 49-51.

Figs. 3, 4 and 5 represent sucrose density gradient patterns for lymph node Fractions 7, 9 and 10, respectively, obtained from a single animal. Antibody activity in Fraction 7 (Fig. 3) was found primarily in fractions 46-48 and 49-51, with small amounts being present in fractions 10-12 and 13-15. Luciferase activity was detected in fractions 7-9, 19-21, 22-24 and 25-27. Antibody and luciferase activities were absent from the pellet. Fraction 9 (Fig. 4) had all its antibody activity in fractions 46-48 and 49-51. No luciferase activity was detected in the gradient fractions, and antibody and luciferase activities were absent from the pellet. As expected, the patterns in Figs. 3 and 4 were similar, since Fraction 9 was the supernatant of Fraction 7. The disappearance of activity from Fraction 7 (fractions 10-12, 13-15 and 46-48) on centrifugation was undoubtedly due to the activity being brought down in

Fig. 2. Sucrose density gradient pattern for spleen Fraction 2

Fig. 3. Sucrose density gradient pattern for lymph node Fraction 7

Fig. 4. Sucrose density gradient pattern for lymph node Fraction 9

Fraction 10. The antibody activity of Fraction 10 was concentrated in the upper regions of the gradient (fractions 40-42, 43-45, 46-48 and 49-51). Some antibody activity was present at the bottom, namely, fractions 1-3, 4-6 and 10-12. Luciferase activity was found in fractions 1-8, 4-6, 7-9 and 10-12. Antibody and luciferase activities were absent from the pellet.

The antibody activity of Fraction 10 was always observed near the top of the gradient in both spleen and lymph node. Occasionally, the activity was found in the lower third of the gradient (not shown). Since the gradient analyses were carried out on Fractions frozen prior to use, a series of gradient patterns were also run on fresh material. Fig. 6 shows the results with Fraction 10 of lymph node. The activity was divided between the top and the pellet, suggesting that freezing and thawing either affect the density or cause a release of activity from the microsomal pellet. The absorbancy and antibody activities, however, were determined on fractions stored overnight at  $-15^{\circ}\text{C}$ . No luciferase was detected in either the fractions or the pellet. Differences in absorbancies may also be seen on comparing Figs. 5 and 6. Virtually the same results were obtained with fresh spleen. Evidently, the active material in the pellet is quite labile to re-suspension. The band-width of antibody activity at the top of the gradient for Fraction 10 was also a little wider in about half the patterns examined than diluted antiserum of approximately equal activity.

The finding that antibody activity is associated with the microsomal fraction is not new and has been reported<sup>1-3</sup> by others. More recently, it has been reported<sup>4</sup> that sucrose gradients of crude ribosomal fractions prepared from spleen cells of immunized rabbits show an 80S-120S peak near the meniscus which is absent in unimmunized rabbits. While the evidence clearly indicates the presence of antibody activity in the microsomal fraction, it is still largely presumptive as to the mode of synthesis or identity of the active material. The

Fig. 5. Sucrose density gradient pattern for lymph node Fraction 10

Fig. 6. Sucrose density gradient pattern for unfrozen lymph node Fraction 10

present work suggests the highest specific antibody activity to be in the microsomal fraction. If sonication is not an important factor, it also suggests that a complex distribution pattern of antigenic and antibody activities develops in spleen and lymph node cells in response to immunization.

# AN IN VIVO CELL SURVIVAL SYSTEM BASED ON THE RECOVERY OF RAT GROWTH CARTILAGE FROM RADIATION INJURY

By DR. N. F. KEMBER

Department of Medical Physics, Royal Free Hospital School of Medicine, London, W.C.1

THE development by Puck *et al.*<sup>1,2</sup> of a single cell culture technique has provided the basis for extensive *in vitro* studies of mammalian cell survival curves. The work of Hewitt and Wilson<sup>3</sup> and of Till and McCulloch<sup>4</sup> has extended these measurements to *in vivo* systems and in this article a further *in vivo* system will be described which is based on the mode of recovery of the epiphyseal cartilage plate following an acute X-irradiation. A dose of approximately 2,000 rads kills a large proportion of the cells in the cartilage plate, but after 10–15 days the few surviving cells start to divide again and form clones of cells that are readily visible in the matrix (Fig. 1). These clones enlarge and coalesce to repopulate the cartilage plate so that the mechanism of endochondral ossification is restored. This recovery process was first described by Dahl<sup>5</sup> in 1936.

3–4 weeks after irradiation it is possible to count the number of clones that arise from cells surviving a given radiation dose. If it is assumed that each clone arises from a single surviving cell then the fractional cell survival can be calculated from the clone count and an estimate of the number of cells in the original population at risk. It is improbable that clones within cartilage could arise from cells that had migrated in from unirradiated tissues in the rat.

Male Wistar rats of 6 weeks of age were taken for experiment. The animals were not anaesthetized during irradiation but were restrained in moulded plastic holders. Both hind limbs were exposed while the rest of the body was shielded with lead. Irradiations were carried out with

230-kV X-rays (0.5 mm copper + 1.0 mm aluminium filtration, half-value thickness 1.2 mm copper), at about 200 rads per min. The dosimetry was carried out with a Baldwin-Farmer thimble chamber placed in the rat mould in the position of the tibia. A factor of 0.95 was used to convert roentgens to rads. During the exposure the beam was monitored for constancy of dose rate and the animals were rotated on a turntable to average out variations in intensity across the beam.

25 days after irradiation the animals were killed and the tibiae embedded in wax. Sections of 10μ thickness were cut in the sagittal plane and from each bone 10 such sections were taken from a ribbon at 100μ intervals and mounted for counting.

Sections from animals killed at age 6 weeks were used in the calculation of the cell population at risk. Cartilage cells in the growth plate are arranged in columns and earlier studies with tritiated thymidine<sup>6</sup> showed that two-thirds of the cells in each column, that is, all those in the proliferating zone, will incorporate tritiated thymidine. If ability to incorporate thymidine is equated with ability to form clones by repeated division, then the number of cells which are at risk in each column can be measured. The total number of columns in the disk-shaped cartilage plate can be estimated by simple geometry from the count of columns across a diameter of the disk. Using the method outlined here the total cartilage cell population at risk in each epiphyseal plate was estimated at  $5 \times 10^6$  cells with a percentage error of about  $\pm 40$  per cent.

The direct method for counting the total number of clones in an epiphyseal plate is by the intercomparison of serial sections. Since this would involve a detailed survey of about 400 sections per tibia an alternative method was used in which an estimate of the total clone number was derived from measurements on a few sections.

On any given section a clone is seen as a roughly circular disk of which the diameter,  $d$ , can be measured, and the thickness,  $t$ , is known from the microtome setting. This disk is a section cut from a sphere of unknown diameter, but the most probable diameter,  $D$ , of the whole clone-sphere is related to the measured diameter,  $d$ , by the relation:

$$D = 4d/\pi$$

Hence the volume of the disk seen on a section may be expressed as a fraction,  $f$ , of the probable whole clone volume:

$$f = \frac{t \cdot \pi \cdot (d/2)^2}{(4\pi/3) \cdot (2d/\pi)^3}$$

The fractional volume per clone,  $f$ , can be summed for all the clones seen in one section  $\Sigma f$ .

Now on each section the cartilage plate appears as a rectangle of width,  $w$ , height,  $h$ , and thickness,  $t$ , which represents a calculable fraction,  $F$ , of the total volume of the disk-shaped cartilage plate:

$$F = \frac{w \cdot h \cdot t}{\pi \cdot (w/2)^2 \cdot h}$$

provided that the sections are selected so that  $w$  is approximately equal to a diameter of the disk.

The total clone number in the complete cartilage plate is given by the relation  $\Sigma f/F$ .

In practice, measurements were made on ten sections and the value of the total clone number for one tibia was taken as the mean of the ten determinations of  $\Sigma f/F$ .

Fig. 1 A recovery clone within the growth cartilage matrix 25 days after 2,000 rads. Longitudinal section of rat tibia, stained haematoxylin and eosin ( $\times 800$ )

One particular difficulty that arises from this method of estimation is the heavy weighting given to small clones. Since the fractional clone volume,  $f$ , varies inversely with the measured diameter of the clone, a small clone contributes proportionally more to the value of  $\Sigma f/F$  than does a large clone. Although this is mathematically correct it introduces large uncertainties into the answer because the smaller a clone is, the more difficult it becomes to recognize as an actively growing group of cells.

Fig. 2 is a semi-logarithmic plot of experimental values for the survival of cartilage plate cells calculated by this method. The points are limited to the dose range of 1,700–2,300 rads since at doses below 1,700 rads there are too many clones to be counted with any accuracy and at doses above 2,300 rads there are too few clones for meaningful analysis. The data are given for experiments on 7 animals at 1,700 rads, 18 at 1,900 rads, 15 at 2,100 rads and 39 animals at 2,300 rads. The standard deviations reveal the wide spread of individual values. Although it cannot be assumed that these points lie on a straight line, in order to make a comparison with other survival data a tentative line has been drawn from an extrapolation number of 6 through the experimental points. The slope of the line,  $D_0 = 190$  rads, is similar to the values obtained from other *in vivo* systems. The value of 6 for the extrapolation number was selected from the results of some split dose experiments of the Elkind and Sutton<sup>6</sup> type.

In theory, this system should be useful for measuring the effect of dose fractionation and experiments were carried out in which one leg of a rat was given a single dose of 2,300 rads while the other leg was given two doses of 1,700 rads and 600 rads with an interval of 24 h between the fractions. The ratio of the clone numbers in the two legs should give the recovery factor for the split dose. Experiments on 6 animals gave a mean value of 6 with individual values varying from 3 to 14. Two other animals had so few clones in the leg given an unfractionated dose that the calculations were unreliable. Fractionation experiments of this type are limited by the narrow range of clone numbers measurable, although the system could be used to measure  $D_0$  (ref. 9), the intercept or quasi-threshold dose, by determining the single dose that produces the same clone number as a split dose. There remains, however, the more fundamental criticism that radiation damage to one leg may well affect the degree of recovery in the other.<sup>10</sup>

The experimental results given in Fig. 2 relate to clone

counts made on animals killed 25 days after irradiation. Clones are seen as early as 10 days after irradiation and an experiment was carried out to discover how the clone number varies with time after irradiation. The results of this investigation are shown in Table 1. There is an increase in clone numbers over the period 21–30 days at 1,900 rads, but this increase is small compared with the variation in individual values. At 2,300 rads no increase in clone number is detectable.

Table 1. VARIATION OF SURVIVING FRACTION WITH TIME AFTER IRRADIATION

Days		21	25	30
Number of animals		9	4	9
Survival after 1,900 rads	Mean	1.4	1.9	2.0
$\times 10^{-4}$	S.D.	$\pm 1.1$	$\pm 0.8$	$\pm 1.4$
Survival after 2,300 rads	Mean	0.25	0.31	0.33
$\times 10^{-4}$	S.D.	$\pm 0.23$	$\pm 0.18$	$\pm 0.30$

It becomes evident when the clones are measured that they vary in type, size and distribution on any one section. The typical clone has an appearance similar to that illustrated in Fig. 1. There is a region of actively dividing cells and a region of hypertrophic cells. In the larger clones the cells are clearly seen to be lined up into the normal columnar arrangement of the cartilage plate. The active process of endochondral ossification is resumed when blood vessels from the metaphysis break through the calcified matrix and invade the hypertrophied cells. Many clones, however, differ from the typical appearance. Some clones contain only dividing cells and others include a large amount of inter-cellular matrix. Some clones contain giant cells and degenerate nuclei and, when clearly recognized, these were classified as abortive clones and excluded from the counts. An abortive clone arises from a cell which divides a few times before latent damage brings division to a stop. Most abortive clones are small in size so that if they are unrecognized and included in the counts they each add an appreciable error to the calculated clone number in a way that has been explained above.

The variations of clone diameter with dose and time after irradiation are analysed in Table 2. The smallest recognizable clones have a diameter of about 40  $\mu$  and clones of this minimum size were found in most of the tibiae. Because the number of clones increases with time (Table 1) the mean clone diameter is not a useful index, but the maximum clone sizes show that there is an increase of diameter with time after irradiation and that clones appear to grow faster after a lower irradiation dose. At any one dose-level and time interval there is a large variation in the sizes of clones measured.

Table 2. VARIATION OF CLONE DIAMETERS WITH TIME AFTER IRRADIATION

Days		21	25	30
1,900 rads	Mean	110 $\mu$	160 $\mu$	170 $\mu$
	Range	40–400	40–600	40–700
2,300 rads	Mean	85 $\mu$	100 $\mu$	180 $\mu$
	Range	40–200	40–400	50–800

The distribution of clones within the volume of the cartilage plate is not random. Looking on the plate as a thin disk, the possibility of variations in distribution within the thickness (200  $\mu$ ) and then across the diameter of the disk (4,000  $\mu$ ) must be considered. The distribution of surviving cells within the thickness of the plate cannot be accurately assessed since many of the clones at 25 days have a diameter of 100  $\mu$  or more and so obscure the site of their origin. An experiment was carried out with 3-week-old rats which have thicker plates and measurements on these animals indicated that clones arose from surviving cells throughout the region of the damaged plate that corresponds to the normal proliferation zone.

A non-homogeneous distribution of clones across the diameter of the cartilage disk was very evident in the sections from animals irradiated with 2,100 and 2,300 rads. The highest density of clones was found at the anterior edge of the plate, and in order to correct for this effect the data at these dose-levels were calculated from counts made over the central 2,000  $\mu$  of the plate. The reason for the apparent increased survival of cells in this

Fig. 2. Cell survival data for rat growth cartilage giving mean and standard deviations of values. Rats breathing air during irradiation

region is not yet clear although three possibilities have been considered.

The first possibility is a local difference in dose compared with the rest of the cartilage plate. This could be produced by variation in the beam across the 4 mm of the plate but such a difference would be small. There could also be an effect at the radiation quality used due to secondary electrons from calcified tissue. The proliferating cartilage cells lie in a 200 $\mu$  thick slab between the epiphyseal bony plate and the partially calcified matrix of the hypertrophied cartilage, but towards the anterior edge the bony plate curves away from the dividing cells. Since few proliferating cartilage cells in any part of the plate are nearer than 30 $\mu$  to calcified tissue it is unlikely that the local dose at the edge could be more than a few per cent lower than the dose at the centre of the cartilage plate. (Data from the International Commission on Radiological Units and Measurements<sup>11</sup> show that the dose beyond 30 $\mu$  from bone is not increased by more than 10 per cent at any quality.)

A further possibility is a local reduction in oxygen tension. Some measurements supported this idea in that some proliferative cells at the anterior edge were as far as 350 $\mu$  distant from their blood supply while the cells in the rest of the plate are no more than 200 $\mu$  distant at maximum.

The third possibility is based on the mechanism by which the cartilage plate normally grows in diameter. Investigations using tritiated thymidine<sup>12</sup> have shown that cells in the fibrous perichondrium differentiate into chondrocytes and add themselves on to the edge of the plate. If these perichondrial cells are more radio-resistant than cartilage cells, or if they can migrate from unirradiated parts of the rat, then there is the possibility that they could form clones at the edge of the irradiated cartilage plate. Further investigations are needed to determine which of these possibilities is effective.

It was stated in the introduction that this method depended on the assumption that each clone arose from a single surviving cell. However, it can be shown from a simple consideration of a Poisson distribution for surviving cells in space that some clones must arise from more than one surviving cell, that is, two or more cells in close proximity give rise to clones that coalesce and are seen as one clone. An analysis of this problem showed that at the maximum clone densities counted this factor was unlikely to introduce an error of more than 20 per cent in the survival values. There remains, however, a possible complication in that adjacent cells in the cartilage plate are partially synchronized in the mitotic cycle since they both arose from the same division. If cells in different stages of the mitotic cycle vary in their sensitivity to radiation then there is an increased possibility of the survival of adjacent synchronous cells.

The recovery of the cartilage plate cannot be considered without some reference to the effects of radiation on the surrounding tissues and the whole animal. For this reason an investigation of the effects of radiation on the vascular supply to the plate was undertaken. Previous work<sup>3,13</sup> on vascular damage to bone has been concentrated on the pronounced changes that occur in the metaphysis, but the cartilage plate is supplied by vessels from the epiphysis. Therefore, these epiphyseal vessels were examined at intervals up to 12 weeks after irradiation by the vascular injection technique using Berlin blue. At doses of 2,000 rads it was found that the supply to the cartilage plate was reduced but not obstructed during this time interval. A parallel approach to the problem of the effect of radiation on the supply of metabolites was made in a brief autoradiographic study with sulphur-35 labelled sulphate; it was found that this metabolite was available to cells in all regions of the plate at times up to 4 weeks after irradiation. It was concluded from these investigations that damage to the vascular supply was not effective in reducing the number of clones.

Fig. 3. Variation in the tibial clone count with the increase in weight of the animal during the experiment. The clone count is expressed as a fraction of the mean clone count for all tibiae having the same radiation treatment.

Endochondral growth is regulated by complex hormonal controls. As a first step in the study of such controls on the recovery of cartilage some correlation was sought between the general health of the animal and the clone count in the tibiae. Some analysis was made using increase in the weight of an animal during the experiment as a crude index of health. The data are presented in Fig. 3. The ordinates represent the clone count for each leg expressed as a fraction of the mean clone count for all legs having the same radiation treatment. The abscissae show the corresponding fractional increase in weight of the animal during the period of the experiment. The points do show the trend that animals with a low weight-gain also show a below-average clone count and that health is one of the factors that affect the clone count in a given animal. This reduced count cannot necessarily be equated with a reduced survival of cartilage cells since the effect of general sickness may be to prevent surviving cells from dividing fast enough to produce a detectable clone by 25 days. It was noted that clones in sick animals were smaller than average in diameter.

This investigation of the recovery of growth cartilage shows that the clone system gives valid, if imprecise, results for cell survival from acute irradiation. It is important to note that the results obtained for cells of growth cartilage may not apply to other types of cartilage, that is, articular and structural cartilage, which both have lower proliferation rates. The system is now being used to investigate oxygen effects on the sensitivity of growth cartilage cells to radiation.

## A STATISTICAL APPROACH TO THE PHILADELPHIA CHROMOSOME

By DR. H. J. WOODLIFF

Department of Haematology, Royal Perth Hospital

DR. LESLEY DOUGAN

Cancer Council of Western Australia

AND

DR. D. W. GOODALL

C.S.I.R.O. Division of Mathematical Statistics, Western Australian Regional Laboratory, Nedlands, Perth

IN chronic granulocytic leukaemia it has been found that one of the small acrocentric chromosomes of the 'G' group is usually smaller than its partner. This has been called the Philadelphia, or  $Ph^1$ , chromosome and its recognition can be used in the diagnosis of this disorder. During a recent investigation of the karyotypes of two patients with megakaryocytic myelosis, a difference of opinion arose as to whether the  $Ph^1$  chromosome was present or not. One member of the 'G' group appeared to be smaller than the other three in both cases and was thought to be the  $Ph^1$  chromosome. Later the material was submitted to an experienced observer who considered that the  $Ph^1$  chromosome was not present in either case. Re-examination of the material led us to revise our opinion and to consider that only one of the two cases was  $Ph^1$  positive. Another independent observer examined the material and agreed that the  $Ph^1$  chromosome was not present in one case, but the other was reported on as follows: Nine out of ten mitoses examined from direct bone marrow preparations showed the presence of a  $Ph^1$ -like chromosome (ref. 1).

As a result of this experience we thought a statistical approach to the problem would be of value. Twelve cases of chronic granulocytic leukaemia considered to be  $Ph^1$  positive<sup>2</sup>, the two cases of megakaryocytic myelosis and nine normal controls have been studied (Table 1).

At first photographic negatives of the karyotypes were projected on to paper and the outline of the 'G' group chromosomes traced. Since then direct projections of the metaphases have been used. The area of each of the four chromosomes was then measured in arbitrary units, using squared paper.

A first attempt at statistical treatment involved the use of Grubbs's test for outliers<sup>3</sup>. In other words, the projected areas of the four 'G' chromosomes in each cell were treated as a sample of a normal distribution, and the ratio of variances including and excluding the smallest chromosome was tested. In most cases of chronic granulocytic leukaemia, however, this test failed to give unequivocal results.

Next, attention was directed to the ratio of the area of the smallest chromosome to that of the others. Two such ratios were examined—that of the smallest to the mean of the other three ( $R_1$ ), and that of the smallest to the next smallest ( $R_2$ ). It would be possible to deduce the distribution of these ratios on the assumption of normal distribution of the four area measurements around a common mean. But such an assumption is of doubtful validity, particularly since the process of measurement leads to a small discrete set of values, and the resulting distributions would, in any event, be awkward functions to handle. Accordingly, it was decided to use empirical

distributions of the ratios in known cases of chronic granulocytic leukaemia and in normal individuals for comparison. It was first ascertained that there were no significant differences in distribution between individuals within each of these two comparison groups, so that all the cells recorded in each group could be treated as a single population. Then the ratios for each of the cases of megakaryocytic myelosis were ranked jointly with those

Fig. 1. Cumulative empirical distribution of  $R_2$ .

for the normal group and those for the chronic granulocytic leukaemia in turn, and Wilcoxon's<sup>4</sup> rank test applied. The results were unequivocal. In Case I, the pattern of 'G' chromosome size differed widely from that of normal cells ( $P=0.002$ ), but agreed satisfactorily with that for chronic granulocytic leukaemia ( $P=0.452$ ). In Case II, the reverse was true ( $P=0.447$  and  $0.008$  respectively). Tests with the two ratios led to similar conclusions; the  $R_2$  probabilities are quoted above. Since  $R_2$  is simpler to calculate than  $R_1$  and there is little difference in sensitivity,  $R_2$  seems preferable.

The Wilcoxon rank test would be a little troublesome to apply on a routine basis, so an alternative non-parametric procedure is proposed. The graphs of Fig. 1 give the cumulative empirical distribution of  $R_2$  for normal cells and for cells from the peripheral blood and the bone marrow of chronic granulocytic leukaemia patients. If the ratios obtained for cells of a case of uncertain status are arranged in order, they may be compared with these graphs by the Kolmogorov-Smirnov test. (Strictly speaking, the Kolmogorov-Smirnov test is applicable only to theoretical distributions; as an approximation, however, its use for empirical distributions based on fairly large samples, as in the present case, may be accepted.) This is best explained by an example. The twelve ratios determined are shown in the first column of Table 2. In the second column are given the proportion of the sample which each ratio equals or exceeds, and in the third and fourth columns are the corresponding figures from the two graphs of Fig. 1. One now looks down the columns to find the largest discrepancy between the two sets of figures. In comparison with the normal

series this occurs in the sixth line and is 0.505; in comparison with the leukaemic series it is in the fourth line and amounts to 0.158. These maximum discrepancies are then compared with figures tabulated (for example, by Owen<sup>5</sup>) for different levels of significance. We find that, for a sample of twelve, a value of 0.375 will be exceeded once in twenty times, a value of 0.449 once in one hundred times. Accordingly we conclude that this particular case is most unlikely to be normal but agrees satisfactorily with a diagnosis of chronic granulocytic leukaemia.

It may be noted that the curve for bone marrow in Fig. 1 for leukaemia patients has a zone of reduced slope in the middle. This agrees with the impression from visual observation that two cell populations may be distinguished in these patients—one with and one without a distinct  $PA^1$  chromosome. Similar statements have been made about cells in peripheral blood, but the resulting bimodality cannot be detected with certainty in its curve.

The  $PA^1$  chromosome is usually found in a higher proportion of cells from preparations of bone marrow than peripheral blood. The distribution of the  $R_1$  ratio for leukaemic patients does in fact differ between these two types of preparation (the Wilcoxon rank test gives  $P=0.014$ ), but the difference for  $R_2$  does not reach significance ( $P=0.140$ ). The means are respectively:

	$R_1$	$R_2$
Bone marrow	0.859	0.781
Blood	0.710	0.795

The smallness of the difference may also be seen in comparing the curves in Fig. 1. For the test described in this article there thus seems little advantage in the use of bone marrow preparations.

## A COMPARISON OF THE GLYCOLIPIDS FOUND IN DIFFERENT STRAINS OF ASCITES TUMOUR CELLS IN MICE

By DR. G. M. GRAY

Lister Institute of Preventive Medicine, London, S.W.1

IN the past few years a number of different complex glycolipids have been found in several mammalian tissues<sup>1-4</sup>. Usually they were detected as very minor components in the total lipid extracts from the tissues though relatively large quantities were found in some diseased tissues<sup>1,4</sup>. Although only a limited number of tissues have been investigated the results have suggested that small amounts of several types of complex glycolipid might be present in most mammalian tissues. All the glycolipids that have been isolated from different tissues contain ceramide (an amide of sphingosine and a long-chain fatty acid) and the differences in their individual physical and chemical properties are due to variations in the size and structure of the carbohydrate moiety of the glycolipid molecule.

The elegant immunochemical studies of Rapport *et al.*<sup>1-3</sup> in recent years showed that certain glycolipids were lipid haptens and that probably all glycolipids possessed hap-

tenic function. The differences in specificity were attributable to differences in the carbohydrate moiety of the glycolipid molecule, and with two compounds, cytolipin H and galactocerebroside (ceramide galactoside), Rapport was able to relate immunological activity to a specific chemical structure. Cytolipin H was first isolated<sup>1</sup> from a human epidermoid carcinoma grown in conditioned rats, and later chemical studies<sup>19</sup> showed that it was a ceramide lactoside. Following up an earlier report<sup>11</sup> on a glycolipid found in ox-spleen, which contained sphingosine, a fatty acid and two sugars, Rapport *et al.*<sup>1</sup> isolated a compound which was chemically and immunologically similar to cytolipin H. Some cytolipin H activity was detected in sheep and dog spleens also, but not in rodent, cat or horse spleens<sup>12</sup>. Although cytolipin H was detected in some normal tissues and was not detected in all the cancer tissues which were examined, Rapport *et al.*<sup>19</sup> stated that it accounted most frequently for the differences observed

between the reactions of lipid extracts of normal tissues and those of cancer tissues on the basis of reactions with antisera against the latter.

Minor amounts of glycolipids were found in the lipid extracts of Landschutz ascites carcinoma cells and BP8 ascites sarcoma cells<sup>13</sup>, and as a result of a more detailed investigation<sup>14</sup> of the glycolipid composition of BP8 ascites sarcoma cells, maintained in C3H mice, four types of glycolipids were isolated and partially characterized as ceramide monohexoside, ceramide dihexoside, ceramide trihexoside and ceramide hexosaminyldihexoside. Similar studies carried out on OL2 ascites leukaemia cells maintained in BALB/c mice showed, however, a very different glycolipid composition (Gray, G. M., and Wells, J. J., unpublished results). The major glycolipid component was identified as a ceramide hexosaminyldihexoside. These findings suggested that tumour specificity and/or mouse specificity might be factors which affected the distribution of the types and the proportions of glycolipids in the tissue. In order to examine further this possibility the glycolipids in several strains of ascites tumour cells were isolated and their compositions compared.

MO1M and SA1 ascites sarcomas were maintained in C3H and A mice respectively, EL4 and OL2 ascites leukaemias were maintained in C57BL and BALB/c mice, respectively, and TA3 ascites carcinoma was maintained in A mice. The mice were bred at the Microbiological Research Establishment, Porton, Wilts., and the growth and recovery of the tumour cells were as described by Davies<sup>15</sup>. The quantities of different freeze-dried cells used ranged from 20 g to 68 g. Each batch of freeze-dried tumour cells was extracted with 3 volumes of chloroform:methanol (1:1, v/v) followed by 3 volumes of chloroform:methanol (2:1, v/v); the two extracts were combined, washed with 0.1 M potassium chloride (0.2 vol.), dried over anhydrous sodium sulphate, filtered and evaporated to dryness *in vacuo*<sup>14</sup>. Each lipid extract was dissolved in light petroleum (b.p. 40°–80°) and dialysed through a rubber membrane<sup>16</sup> against light petroleum to separate the neutral lipids from the phospholipids and glycolipids. The phospholipid/glycolipid fraction was treated with 0.07 N methanolic sodium hydroxide:chloroform (2:1, v/v) to remove the diacyl glycerophospholipids as water soluble phosphate esters<sup>17</sup>. The fatty acid methyl esters formed in the reaction were separated from the alkali-stable phospholipids and glycolipids by dialysis through a rubber membrane. The approximate composition of each alkali-stable lipid extract was determined by chromatographing samples on silicic acid impregnated paper<sup>18</sup> and silica-gel G (Merck) thin-layer plates<sup>14</sup>. At this stage the lipid extracts from all the strains of tumour cells contained at least eight components and in each case the major one was sphingomyelin, the main contaminating phospholipid.

Previous work<sup>14</sup> showed that the standard procedure for the removal of phospholipids from a glycolipid fraction by adsorption on Florisil<sup>19</sup> was unsuitable for lipid extracts from ascites tumours and better results were obtained with alumina<sup>20</sup>. The lipid extract was loaded on to an alumina column (0.5 mg phosphorus/g alumina) in chloroform:methanol (1:1, v/v) and fractions were collected from the column and monitored by thin-layer chromatography. Most of the phospholipid (sphingomyelin) was eluted from the column with the same solvent. The solvent was changed to chloroform:methanol:water (10:10:1, by vol.) and the water content was gradually increased from approximately five up to ten per cent.

The glycolipids were eluted with solvent containing a water concentration within this range. The fractions from the column were combined according to their composition as indicated by thin-layer chromatography and these fractions were analysed for phosphorus and carbohydrate<sup>14</sup>. The glycolipids from each of the five strains of ascites tumour still contained small amounts of phosphorus after alumina chromatography and, with the exception of the glycolipid fraction from SA1 ascites tumour, these were successfully removed by passing each fraction dissolved in chloroform:methanol:water (2:5:2 by vol.) through a small column of Deacidite FF (anion exchange resin) in the same solvent. The yield of glycolipids obtained from each strain of ascites tumour was very small (Table 1) and it was impractical to attempt to separate individual glycolipids on a quantitative basis. However, the glycolipid compositions of the five different ascites tumours were compared after thin-layer chromatography of the total glycolipid fractions on silica-gel G (Merck) with a

Fig. 1. a, The separation into individual classes of the glycolipids present in different ascites tumours in mice by thin-layer chromatography on silica-gel G (Merck); solvent system, chloroform:methanol:water (65:25:4, by vol.). Plate was sprayed with 5 per cent phenol/60 per cent sulphuric acid (1:1, v/v). b, Identification of components by comparison with known glycolipid markers (A): (1) ceramide glucoside; (2) ceramide lactose; (3) ceramide digalactosylglucoside; (4) ceramide *N*-acetyl-galactosaminyldigalactosylglucoside; (5) ceramide *N*-acetylgalactosaminyldigalactosylglucoside; (6) ceramide *N*-acetylgalactosaminyldigalactosylglucoside; (7) ceramide *N*-acetylgalactosaminyldigalactosylglucoside. A, Glycolipids from EL4/C57BL ascites leukaemia; B, SA1/A ascites sarcoma; C, OL2/BALB/c ascites leukaemia; D, MO1M/C3H ascites sarcoma; E, TA3/A ascites carcinoma. Components 6 and 7 are probably glycolipids containing larger carbohydrate residues than 5 or sialic acid.

Table 1

Ascites tumour/ mouse	Amounts of lipids isolated from ascites tumour cells calculated per 100 g freeze- dried cells			Glycolipids % by wt of total lipids
	Neutral lipids (g)	Phospholipids (g)	Glycolipids (mg)	
MO1M/C3H	8.6	5.5	41	0.20
TA3/A	10.0	6.8	37	0.16
SA1/A	6.0	6.2	7	0.06

OL2/BALB/c	6.0	7.2	64	0.48

solvent system of chloroform:methanol:water (85:25:4). Ceramide monohexoside, ceramide dihexoside, ceramide trihexoside, ceramide hexosaminyldihexoside and ceramide hexosaminyltrihexoside were chromatographed at the same time for reference purposes. The solvent front was allowed to travel about four-fifths of the plate height, the plate was dried and sprayed with 5 per cent phenol: 60 per cent sulphuric acid (1:1, v/v) and heated at 120°. The glycolipids showed up as purple-brown spots.

There was a considerable variation in the composition of each strain of tumour (Fig. 1 a, b). The major component in *MO1M*, *EL4* and *SA1* was a ceramide monohexoside, in *TA3* a ceramide dihexoside and in *OL2* a ceramide hexosaminyldihexoside. This particular glycolipid, which was characterized as ceramide *N*-acetyl-galactosaminylgalactosylglucoside (Gray, G. M., and Wells, J. J., unpublished results), occurred only in the *OL2* ascites tumour, but this strain did not contain ceramide trihexoside nor ceramide hexosaminyltrihexoside, both of which were present in the other strains of tumours. (The glycolipid fraction from *SA1* contained a phospholipid contaminant which had similar chromatographic properties (Fig. 1) to ceramide trihexoside and it was not possible, therefore, to confirm the presence of the glycolipid in this strain.) *OL2*, *MO1M* and *TA3* also contained significant amounts of two glycolipids (Fig. 1b (6 and 7)), which, by their chromatographic behaviour, had carbohydrate residues which were either larger than a tetrasaccharide (Fig. 1b (5)) or contained sialic acid.

The 'double spot' obtained for each glycolipid component after thin-layer chromatography on silica-gel *G* (Merck) represented a separation of glycolipids containing normal straight chain fatty acids from those containing hydroxy fatty acids\* (the slower moving component). Most of the glycolipids (Fig. 1) contained hydroxy fatty acids, and in several cases the hydroxy compounds appeared to be present in amounts equalling those of the normal straight chain fatty acids. The apparent proportions of glycolipids containing mono-, di-, tri-, and tetrasaccharide moieties in the *MO1M* ascites sarcoma maintained in *O3H* mice were similar to those reported<sup>14</sup> for *BP8* ascites sarcoma also maintained in *O3H* mice. However, the proportions of the glycolipids in *TA3* ascites carcinoma and *SA1* ascites sarcoma, both maintained in *A* mice, were quite different (Fig. 1), and thus mouse specificity does not seem to be a factor controlling the general composition of the glycolipids. It is important to realize that although the differences in the proportions of glycolipids present in different strains of tumours and mice may not be a function of tumour or mouse specificity small variations in the fine structure of each glycolipid, such as a different linkage between two sugar residues, may be so related. There is no doubt that subtle differences do exist. Rapport (personal communication) tested the lipid extracts from *BP8*, *OL2*, *EL4*, *SA1*, *TA3* and Landschutz ascites tumours for cytolipin *H* activity by the very sensitive immunochemical technique<sup>7</sup> and found that only the *BP8* ascites tumour lipids contained cyto-

lipin *H* (ceramide lactoside; compare Gray<sup>14</sup>). It has been shown that all these tumours contain a ceramide dihexoside (Fig. 1) and so it is concluded that the structures of the dihexosides in the tumours other than *BP8* (*MO1M* was not tested) are different from lactose. A ceramide digalactoside<sup>14</sup>, which was found in the *BP8* ascites tumour as well as ceramide lactoside, may be the dihexoside present in some of the other tumours. Differences within a particular class of glycolipid may be the result of variations in the linkage of one sugar to another. A glycolipid has been isolated from *OL2* ascites tumours and identified as a ceramide galactosylglucoside (Gray, G. M., and Wells, J. J., unpublished results); however, as no cytolipin *H* activity was found in the lipid extract from *OL2* tumours it seems likely that the galactose to glucose linkage is not  $\beta(1\rightarrow4)$ . If the glycolipids containing di-, tri-, and tetrasaccharide residues have related pathways of biosynthesis<sup>14</sup>, the structural differences which appear to exist between the ceramide dihexoside from different ascites tumours may also occur in the glycolipids containing the larger carbohydrate residues.

The isolation of the glycolipids in quantities which are necessary for the identification of their chemical structures has not been possible because of lack of tumour material. The problem of insufficient material may not be so serious in the future if a variety of glycolipids within the classes described in this article can be synthesized<sup>11</sup>; with these compounds of known structure available the immunochemical technique described by Rapport would provide an excellent means of characterizing the glycolipids in very small amounts of tissue.

I thank Dr. D. A. L. Davies for a gift of various tumour cells, and the British Empire Cancer Campaign for Research for supporting this work.

## GENETIC PROPERTIES OF EXOGENOUS DEOXYRIBONUCLEIC ACID AT VARIOUS LEVELS OF DEGRADATION IN *Drosophila melanogaster*

By DR. O. G. FAHMY and DR. MYRTLE J. FAHMY

Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital, London, S.W.3

THE injection of deoxyribonucleic acid (DNA) into the haemocoel of adult *Drosophila* males was shown<sup>1</sup> to initiate the induction of small chromosome deletions resulting in the *Minute* phenotype. The same activity was later detected with a diversity of natural<sup>2</sup> and syn-

thetic<sup>3</sup> macromolecules, such as ribonucleic acid (RNA), deoxyribonucleoproteins (DNP), representative of acidic, basic and neutral proteins (albumins, histones and globulins), as well as some anionic polymers (polynucleotides, polyglutamic acid, polymethacrylic acid). None of

these agents possessed any chemical reactivity which could have resulted in direct damage to the genetic material. Their mutagenic action must have accordingly been indirect, and it was possible to infer<sup>3,4</sup> that the underlying mechanism involved disturbances in DNA synthesis during chromosome replication, as a consequence of the inhibition of some of the requisite enzymes.

In contrast to the activity of DNA in the production of chromosome deletions, it was completely ineffective in the mediation of specific locus transformation and gave weak and rather inconsistent activity as regards the induction of sex-linked recessive visibles and lethals<sup>1,2</sup>. The negative results with transformation could have been the outcome of the physiological incompetence of the tested samples of DNA, perhaps as a result of their partial degradation. Conversely, the inconsistent activity as regards the point mutations might have been the outcome of insufficient DNA degradation, if mutagenicity was not due to the polymer itself, but to the nucleotides and nucleosides derived from its intracellular breakdown. Some of the samples of *Drosophila* DNA used in the earlier genetic experiments<sup>1</sup> were extracted<sup>1</sup> from developing embryos (before egg hatching) and were of low viscosity, which suggested a certain degree of degradation. More recently, better methods of DNA extraction from the adult flies were developed<sup>7</sup>, which yielded samples of larger molecular size, thus warranting the repetition of the transformation tests. For the mutagenicity tests, the large DNA molecules were artificially degraded by ultrasonics or high doses of  $\gamma$ -rays. The results with irradiated DNA were of significance not only to the understanding of the polymer's mechanism of action, but also in relation to the problem of genetic hazards to man that might arise as a result of food sterilization by ionizing radiation. The possibility of such hazards has been indicated by a recent report<sup>11</sup> that an irradiated sample of DNA was highly mutagenic in *Drosophila*, particularly as regards the induction of sex-linked recessive lethals. A comparative examination was accordingly undertaken of the mutagenic activity of untreated and degraded DNA (both by sonication and irradiation) as regards the induction of chromosome deletions and point mutations, and the results are presented in this article.

The DNA samples used in the work recorded here were all extracted from the adults of *Drosophila melanogaster* ('Oregon-K' strain) by our colleagues, Hastings and Kirby<sup>7</sup>. In principle, their procedure involved the preliminary separation of RNA, by the use of naphthalene-1,5-disulphonate and phenol/8-hydroxyquinoline<sup>12</sup>, followed by the isolation of DNA by the *p*-aminosalicylate/phenol technique<sup>8</sup>. Purification and concentration of the isolated DNA were undertaken with minimal exposure to low ionic concentration and organic solvents, so as to reduce molecular fragmentation. Physico-chemical measurements (viscosity, sedimentation patterns and melting curves) on the isolated material indicated a homogeneous and satisfactory order of molecular integrity. DNA samples with the largest obtainable molecular size (mol. wt.  $\approx 4 \times 10^6$ , as estimated from sedimentation velocity experiments) were used for the transformation experiments and some of the mutagenicity tests. The material was dissolved at the required concentration in isotonic saline (0.4 per cent sodium chloride) and administered by micro-injection into the haemocoel of adult males, immediately around their testes. Aliquots of the same sample of DNA were then subjected to the degradation procedures and their mutagenic activity was reassayed by the same genetic techniques as with the untreated material. For degradation by ultrasonics, a DNA solution of high concentration (0.5 per cent w/v in isotonic saline) was cooled in an ice bath, and subjected to short-wave sound waves (20 kc/s/60 W) for 3 min; the sonicated material was then heated in a water bath (100° C) for 10 min. After this treatment the initial DNA solution virtually lost its

viscous consistency and was found to contain DNA fragments of fairly small size (mol. wt.  $\approx 200,000$ ). For degradation by radiation, a DNA gel (1.0 per cent, w/v in isotonic saline) was subjected to  $\gamma$ -rays (from a cobalt-60 source) at a dose rate of 1,370 r./min for 2 h 50 min, corresponding to a total dose of 232,900 r. After irradiation, the DNA gel was changed into a somewhat viscous hydrosol, and was found to contain larger fragments of the polymer (mol. wt.  $\approx 500,000$ ) than after sonication and boiling.

The genetical techniques used in the investigation recorded here have already been described in detail elsewhere<sup>1-4</sup>. Transformation was examined at seven recessive loci: *yellow* (*y*), *vermillion* (*v*), *miniature* (*m*) and *forked* (*f*) on the X chromosome; *brown* (*bw*) on the second, *ebony* (*e*) on the third, and *polster* (*pol*) on the fourth chromosomes. The detection of the mutations was undertaken by the attached-X technique for the visibles—both sex-linked recessive and autosomal dominants (especially *Minutes*); and by the Muller-5 method for sex-linked recessive visibles and lethals. In all the mutagenicity tests the treated males were repeatedly mated to an approximately equal number of females every three days, and the mutation rate in each brood was determined separately. Breeding was undertaken in mass cultures, with a maximum of ten pairs per half-pint bottle.

In previous transformation experiments<sup>1</sup>, DNA was extracted from the wild-type flies and injected at various concentrations into males homozygous for the 7-mutant (abbreviated 7-*m*) marker stock. With this technique it would be possible to detect the displacement of the mutant loci by the wild-type alleles from the administered DNA. In the event of successful transformation, homozygosity at the affected site would be changed to heterozygosity, which would lead to reversion to the wild-type expression at the transformation site—because of the recessiveness of the marker genes. In fact, no such revertants were observed, either in earlier experiments with somewhat degraded DNA, or in the more recent ones with better samples of the polymer. The total chromosomes carrying the test markers which were exposed to the various samples of DNA from the wild-type flies were accordingly pooled (+DNA in 7-*m* flies, Table 1) to give an idea about the size of sample which failed to incorporate wild-type DNA instead of the mutant genes. The improved DNA samples were also used to test for the reverse transformation: the incorporation of mutant DNA in place of the wild-type genes. For this purpose, DNA was extracted from the stock homozygous for the 7-mutant loci and injected into wild-type males. These were then crossed to females homozygous for the multiple recessive markers and their progeny were scored for any of the mutant phenotypes. In the event of specific locus transformation, the mutant DNA segment from the extract replaces its wild-type allele in the genome of the treated male and is later rendered homozygous by the back-cross to the marked female, thus revealing the mutant phenotype of the transformed gene. No such transformants were detected (7-*m* DNA in + flies, Table 1) at any of the test loci,

\* Assuming passive transfer of DNA by the sperm.

† Male progeny receiving the marked maternal X-chromosome, which precludes scoring for transformants.

thus showing that exogenous DNA (whether normal or mutant) was not readily acceptable for incorporation into metazoan cells—as genetically functional units. On the basis of the negative results so far obtained (last column, Table 1), the probability of transformation per locus in the germ line of *Drosophila* cannot exceed  $2 \times 10^{-6}$  (the upper limit of the Poisson expectation at  $P = 0.025$ ).

The administration of mutant DNA into wild-type males, although ineffective as regards transformation, showed signs of mutagenic activity as regards the induction of point mutation visibles. Among the male progeny from the back-cross of the DNA-treated fathers to the multiple recessive mothers, ten eye-colour mutants were detected through their interaction with *vermillion* (*v*), which resulted in various shades of orange eyes. Genetic analysis of these abnormal males revealed that in four instances the induced mutants were alleles of the sex-linked recessive visible *garnet* (*g*); three others were autosomal dominants, and the remaining three were with large rough eyes and proved sterile. The *g*-mutations were in the multiple marked maternal X-chromosome and could, therefore, have occurred either spontaneously, or indirectly through the passive transfer of DNA—which was injected in the males—via the sperm during fertilization. The four *garnet* instances were recovered from separate cultures and broods, indicating that they arose as independent mutational events. The maternal X-chromosomes (among which the *g*-mutants occurred) would be passed to their sons, the number of which was 62,807 (X-chromosomes exposed in zygotes only, Table 1). The mutation rate at the *g*-locus would, therefore, be  $6.4 \times 10^{-4}$ , which is considerably higher than the spontaneous rate and is equivalent to that occurring after 1,500 r. of X-irradiation<sup>5</sup>. There can be no doubt, therefore, that the mutants observed were not of spontaneous origin, and must accordingly have been induced by DNA conveyed at fertilization with the treated sperm.

Attention has already been directed<sup>1</sup> to the possibility that the mutagenic activity of DNA might depend on the degree of its molecular integrity. For the same sample of DNA, the mutagenic activity—as regards the *Minutes*—was roughly proportional to the injected concentrations. On the other hand, different samples at the same concentration gave various mutagenic activity and there were indications that the larger DNA molecules were less effective. To test this possibility, a comparison was undertaken of the mutagenic activity of untreated DNA relative to that of samples degraded by ultrasonics and  $\gamma$ -radiation. The mutagenic activity, as regards small chromosome deletions (*Minutes*), was significantly above the control level with all the three tested samples, but was markedly higher with the degraded DNA (whether sonicated or irradiated) than with the untreated materials (Table 2). The rate of *Minutes* with the present sample of undegraded DNA was not significantly different from that induced by the same concentration (0.5 per cent) of a previous sample extracted from adults by the same chemical procedure<sup>7</sup> (ref. 2, Table 1). This activity, how-

ever, was considerably lower than that expected for the same concentration of embryonic DNA, which was extracted by a different isolation technique<sup>8</sup>. In fact, the mutagenicity of the embryonic DNA sample was of the same order as that of the sonicated material in the work recorded here, suggesting that it was degraded by the isolation technique then used. This demonstrated the superiority of the recent extraction method from adults, which yielded larger DNA molecules of lower mutagenic effect. It should also be noted that there was no marked difference in the rate of *Minutes* with the sonicated and irradiated DNA, in spite of the higher concentration of the irradiated material. This again might be a function of various degrees of degradation, since the irradiated sample contained larger fragments of DNA than after sonication.

Table 3. THE SEX-LINKED RECESSIVE LETHALS (l) AND VISIBLES (v) INDUCED BY SONICATED OR IRRADIATED DNA DETECTED IN THE F<sub>1</sub> PROGENY FROM MULLER-5 EXPERIMENTS (Mosaic mutants entered in brackets)

In contrast to the decisive activity of DNA in the induction of small chromosome deletions resulting in *Minutes*, our previous work<sup>1,2</sup> yielded no consistent evidence for the polymer's activity in the production of point mutations (sex-linked recessive visibles and lethals). This has now been ascertained for the degraded samples as well, by both the attached-X and Muller-5 techniques. The rate of the sex-linked recessive visibles in the attached-X tests was the same with the undegraded and degraded DNA and did not differ significantly from the control level (Table 2). In the Muller-5 tests, no visibles were recovered with the sonicated DNA; but the irradiated material induced two mutants in 1,777 chromosomes (Table 3), which is above the upper limit of the Poisson expectation ( $P = 0.025$ ) on the basis of the spontaneous visible rate. Comparable positive results as regards the induction of visibles have previously been encountered with unirradiated DNA (ref. 1), which suggested that these mutations could rarely be induced in the presence of the polymer, under appropriate cellular conditions. On the other hand, the sonicated and irradiated DNA (Table 3), like the untreated material<sup>1,2</sup>, were completely ineffective in the induction of sex-linked recessive lethals; the mutation rate in this respect was the same as among the progeny of males injected with isotonic saline.

The results presented here showing the inactivity of degraded homologous DNA, as regards sex-linked recessive lethals, are in clear contradiction with Parkash's report<sup>11</sup>

that these mutations were produced at a high rate (5.7 per cent) among the progeny of flies fed with an unspecified sample of irradiated DNA (presumably heterologous). This mutagenic activity was stated to be the direct effect of the irradiation products of DNA, and was attributed to the incorporation of parts of the macromolecule into the nuclei of the fly's germ line. Great care was accordingly taken in the design of the present experiment with irradiated DNA, to favour the induction of recessive lethals, on the basis of Parkash's proposals. Homologous DNA was used, in the hope of favouring exchange between the exogenous material and the genome of the germ cells.

Degradation of DNA was undertaken by its exposure in the gel-state to a massive dose of  $\gamma$ -rays ( $> 230,000$  r.), which was more than double that used by Parkash. The irradiated DNA was immediately injected around the males' testes, in the hope of capturing any metastable mutagenic compounds that might have resulted from irradiation. The injected males were tested throughout the full period of their fertility, so as to ensure the recovery of sperm treated in the spermatocytic and spermatogonial stages. These were the cells predominantly exposed to the treatment (in the larval testes) with Parkash's feeding procedure, and they would be sampled with the brood technique used in the present work on injected adults in the fourth and later broods, more than 9 days after treatment<sup>4</sup>. In spite of these precautions, the irradiated DNA showed no signs of activity—as regards sex-linked recessive lethals—either in the early or in the late progeny (Table 3). The results in the fourth and later broods were of particular interest, since they showed the response of the early sector of the germ line. The progeny in these broods was invariably low with the higher injected doses of all the tested macromolecules<sup>1-3</sup>, because of their preferential cytotoxicity on the metabolically active early germ cells. Nevertheless, in the Muller-5 test with irradiated DNA, it was possible to recover 511 chromosomes after the ninth day of treatment, the majority of which must have been treated in the meiotic and premeiotic stages. If mutagenic response to irradiated DNA was restricted to these stages, the tested X-chromosome sample would be expected to contain a minimum of 19 lethals (the lower limit of the binomial expectation at  $P = 0.025$ ) on the basis of its reported<sup>11</sup> activity (5.7 per cent); instead none was observed. There can be no doubt, therefore, that the recessive lethals which occurred in Parkash's experiment were not the direct outcome of the incorporation of DNA fragments (released by irradiation) into the genome of the fly's germ line. The possibility still remains, however, that the DNA irradiation products might have been metabolically converted into mutagenically active derivatives as a result of their passage through the flies' alimentary canal. This possibility is now under investigation, in view of its implications as regards human genetic hazards after food sterilization by ionizing radiation.

The demonstration of the higher activity of degraded DNA in the induction of *Minutes* suggested that its mutagenicity might—in part at least—be due to its intracellular breakdown to the constituent nucleotides and the corresponding nucleosides after dephosphorylation. In support of this possibility were the recent results<sup>4</sup> with the nucleosides of pyrimidine analogues: the 5-halogen derivatives of deoxyuridine—FUDR, BUDR, IUDR; cytosine arabinoside, 6-azauridine, and 6-azacytidine. All these compounds showed the DNA type of mutagenicity, in so far that they were mainly effective in the induction of *Minutes*, were rarely active for recessive visibles and inactive for lethals.

From a comparison of the biochemical and mutagenic properties of the tested nucleosides, it was possible to deduce that mutagenicity was the outcome of the shortage of particular nucleotides, through the specific inhibition

of the enzymes required in their synthesis. A slight disturbance in this way would be expected to result in the loss of one—or a few—nucleotides during the synthesis of genomic DNA, thus resulting in point mutations (recessive visibles). On the other hand, a drastic metabolic disturbance at the nucleotide level would upset the balance between the four requisite DNA precursors, thus blocking polymerization and resulting in the loss of whole molecules, and the eventual induction of chromosome deletions. A comparable disturbance in the optimal equilibrium between DNA precursors might well arise as a result of intracellular accumulation of the polymer's degradation products, which could lead to the same errors in the polymer's synthesis and the associated mutagenic effects. It seemed, however, that the natural nucleosides (derived from DNA degradation) produced the slight metabolic disturbances (nucleotide losses) more frequently than their synthetic analogues, since there were more point mutation visibles after DNA injection than with the tested pyrimidine nucleosides. It is most unlikely, however, that the whole of the biological activity of DNA is due to its degradation products. An appreciable rate of *Minutes* occurred with fairly undegraded DNA, as well as with various synthetic polymers, some of which (like polymethacrylic acid) were known to be completely resistant to intracellular enzymatic degradation. This suggested that, at least in so far as chromosome deletions were concerned, part of the DNA effect was produced while the molecule was still in some polymeric state. Its mutagenic effect in such a state—as with other polymers—was probably due to generalized inhibition of cellular enzymes, including some of those involved in DNA synthesis.

To conclude, the results presented here with intact (untreated) as well as degraded DNA (treated with ultrasonics or irradiation) confirmed and supplemented our previous results<sup>1-3</sup> concerning the genetic mode of action of this macromolecule in metazoan cells. Specific locus transformation was unsuccessful, both with wild-type and mutant DNA, even with samples of fairly large molecular size. In contrast, DNA at various levels of degradation was decisively active as regards the induction of small chromosome deletions (*Minutes*), weakly active for the recessive visibles, but completely inactive for the recessive lethals. Evidence was found indicating that DNA mutagenicity could be produced indirectly, through its passive conveyance by the sperm during fertilization and the subsequent induction of mutation in the course of chromosome replication at cleavage: mutants occurred in the maternal X-chromosome when treatment was restricted to the paternal germ line. Degradation of DNA, by ultrasonics or  $\gamma$ -radiation, did not alter the type of mutations induced, but only increased the mutagenic efficiency as regards the induction of small chromosome deletions (*Minutes*).

We thank Prof. A. Haddow for his advice, and Drs. K. S. Kirby and J. R. B. Hastings for their efforts to improve the techniques for the isolation of *Drosophila* nucleic acids.

# LETTERS TO THE EDITOR

## RADIOPHYSICS

### Lunar Occultation of the Radio Source CTA 21

THE radio sources CTA 21 and CTA 102 have been of considerable interest since they were first reported by Harris and Roberts<sup>1</sup> from observations at 958 Mc/s. Later work<sup>2</sup> showed that the radio spectra of these sources differed from those of most other sources and that each source had a maximum of emission near 900 Mc/s. It has been suggested<sup>3,4</sup> that this form of spectrum is produced by self-absorption of synchrotron radiation within a source of small angular size, and from the shape of their spectra the very small angular diameters of  $\sim 0.01$  sec of arc have been predicted for both CTA 21 and CTA 102. CTA 102 has recently been identified<sup>5</sup> as a quasi-stellar radio source, but for CTA 21 no optical object can be detected on the 48-in. Sky Survey plates within the limits of error ( $\pm 6$  sec of arc) of the existing radio source position<sup>6,7</sup>. It appears that an identification of CTA 21 with an optical object can only be made if the radio source position is more precisely known and the region of sky can be examined with more powerful optical techniques.

An opportunity to measure an extremely precise position for the source has been presented by the series of lunar occultations which occurs during 1964-65. No further occultations of this source will then be observable for several years. Two occultations were predicted for the C.S.I.R.O. radio telescope at Parkes, Australia. The first occurred close to the local horizon and could not be observed, and even on the second occasion (February 9, 1965) only the disappearance of the source occurred within the normal working altitude range of the telescope.

This disappearance was observed at 2,650, 416 and 154 Mc/s. The measurements at 2,650 Mc/s showed well-

defined Fresnel diffraction fringes, and preliminary calculations suggest that the source is single and that it has a radio diameter of less than 1.5 sec of arc. This result is consistent with that obtained from some recent interferometer measurements<sup>8</sup> which have shown that the source has an apparent diameter  $< 0.4$  sec of arc. Re-appearance occurred  $8^\circ$  below the altitude limit of the telescope and was observed at 154 Mc/s only with an offset feed. Even at this frequency the measured signal-to-noise ratio was appreciably reduced from the on-axis observations and no useful off-axis observations could have been made at the higher frequencies. The use of off-axis observations and the low flux density of the radio source at 154 Mc/s have meant that the signal-to-noise ratio and hence the accuracy of timing are much poorer at the re-appearance than at the disappearance.

The measured times are given in Table 1.

Table 1	
Disappearance	10h 10m 47s.8 $\pm$ 0s.5 U.T.
Re-appearance	11h 28m 02s.5 $\pm$ 0s.5 U.T.

These times correspond to a position of the radio source of R.A. 03h 16m 9s.11, Dec.  $16^\circ 17' 40''.3$  (1950.0). A value of 33s.5 has been assumed for the difference between ephemeris and universal times in order to bring the deduced position on to the FK3 system<sup>9</sup>. The source position together with the limits of error are shown in Fig. 1.

It is understood that no object can be seen in the new radio position on the best existing plates which have been taken with the 200-in. telescope on Mount Palomar.

We thank Mr. B. F. C. Cooper and many others on the laboratory's staff for their assistance with the observations, and Mr. W. Nicholson of H.M. Nautical Almanac Office for sending details of the circumstances of the occultation.

## PHYSICS

### A New Role for the Electrophorous

THE electrophorous<sup>1</sup> consists of a flat polymeric plate placed in contact with a flat metal plate. The two surfaces are separated only by the higher asperities of the surfaces and so actual contact is only made at a few points. If the polymer surface has been previously negatively charged by the diffusion of electrons into it, then the metal will be negatively charged at the few places where contact is made and positively charged by induction where there is no contact. If a time-varying dynamic load is now applied to the system so that the plates never lose contact and the variation of the distance between them is due to the elastic deformation of the asperities, then there will be time-dependent variations in the induced electrostatic charge on the metal plate. If the

Fig. 1. Diagram showing the mean position (+) of the radio source CTA 21. The limits of error are defined by the range of possible positions of the limb of the Moon allowed by the uncertainties in the measured times of disappearance and re-appearance

induction effects predominate, then it is of interest to measure the current flow to, and from, the plate when it is connected to earth through a high-resistance voltmeter or oscilloscope.

In these investigations a charge is put on the polymer surface by heating in contact with a metal surface at the softening point of the polymer and then applying a static pressure which just deforms the polymer. This process is considered to be the most promising for investigation because the initial electrification action must be electronic diffusion from metal to polymer at the softening temperature.

Although simple to manufacture, it seems likely that the electrical response of the system to a dynamic load may be complicated. This has therefore been subjected to preliminary experimental investigation using the pressure bar method to apply dynamic pressures. A steel rod 2.5 cm diameter and 120 cm long with plate ends is supported horizontally. Longitudinal impact by a 2.5 cm diameter steel sphere, which is suspended as a simple pendulum, produces a stress wave pulse in the rod. The maximum pressure corresponding to a given height of fall of the impactor is obtained from the results of Barton *et al.*<sup>2</sup>

In the present high-pressure experiments the polymer used is polymethylmethacrylate (PMMA). The transducer unit tested using the pressure bar consists of a (PMMA) plate 2.5 cm  $\times$  2.5 cm  $\times$  0.1 cm cemented on to one of the two plane end faces of a short cylindrical steel rod which is 5 cm long and 2.5 cm diameter. Electrostatic charge is then produced on the free PMMA surface as described here. A clean tin foil is next cemented on to the face of a polymer block 2.5 cm  $\times$  2.5 cm  $\times$  1.0 cm. The free tin and charged PMMA surfaces are put in contact and the parts clamped together under a small static compressive force. The unit is then wrung on to the measuring end of the pressure bar and a compressive stress pulse generated by the impactor. The maximum pressure in the stress pulse is much greater than the static pressure. The voltage-time signal recorded from the unit consists of an initial pulse followed by a wave train which decays in amplitude.

The maximum voltage of the initial pulse is compared with the maximum stress pulse pressure for heights of fall,  $h$ , of the impactor over the range 1–15 cm. Up to  $h \approx 10$  cm, corresponding to a maximum pressure of  $70 \times 10^4$  dyn/cm<sup>2</sup>, the experimental observation is that maximum pressures and voltages are directly proportional. Since pressure is proportional to the velocity of the measuring end of the bar<sup>3</sup>, that is, the charged PMMA surface, then it follows that the recorded maximum voltage or current is directly proportional to the velocity with which the charged PMMA surface moves towards the metal surface during dynamic compression.

The value of this experimental result is that it makes possible the application of electrostatic properties to the development of electrical devices which can be used to investigate any continuous mechanical vibration. Various types of dynamic electromechanical transducer, which utilize electrostatic properties in conjunction with the wide range of polymer mechanical properties, are being considered for the examination of the dynamic forces in impact problems, and acoustic vibrations.

Further possibilities for the utilization of electrostatic surface charges initiated by electronic diffusion are being explored.

## Distribution of Near Neighbours in a Random Packing of Spheres

DURING some work on the tensile strength and cohesion of wet particles, it became necessary to have some knowledge of the number of contacts and near contacts existing in a random packing of equal spheres. The range of centre to centre separations from 1.0 to 1.3 diameters was of particular interest to this work because experimental results had shown that liquid bridges existing between spheres separated by these distances were likely to play a major part in the cohesion of a wet bed of spheres<sup>1</sup>.

Both Bernal<sup>2</sup> and Scott<sup>3</sup> have measured radial distributions in packings of spheres for use in their work on liquid structures. However, they were both concerned with a somewhat greater separation range, and their results lack the necessary detail in the narrow range required here. To obtain some additional information in this range the following experiment was performed. One thousand and six good-quality table-tennis balls, diameter 1.5 in., were placed in a polythene bag, and the whole was buried in sand. The sides of the bag had been randomly deformed to prevent systematic packing on the outside of the system. The bag was then filled with a 2 per cent w/v agar solution at 45° C which filled the spaces between the balls. The balls were prevented from floating up in the solution by weighting the top of the assembly. The agar was allowed to set at room temperature, and the complete assembly removed from the bag. The balls were removed one at a time. As each sphere was removed the number of contacts was counted, and the distance of any near neighbours measured through the agar with a simple needle-type probe. This was a direct measurement with an accuracy of 0.25 mm. The total number of contacts and the distribution of near neighbours are counted for the whole bed. The values obtained for the outer layers did not differ significantly from the values for the central core, consequently all the counts are included in the results. These are plotted in the co-ordinates used by Scott in Fig. 1. This illustrates the high incidence of actual contacts, and shows the significant number of non-touching near neighbours lying in the range 1.0–1.3 diameters. An interesting point is the appearance of an apparently significant small peak in the region of 1.22 diameters. The overall packing density of the bed was measured and the limiting value at large values of  $r$  is shown in Fig. 1.

Fig. 1. Histogram of  $N_n/4\pi r^2$  versus  $r$ .  $N_n$  is the average number of spheres in an interval of 0.0656 (0.25 mm) sphere diameters at a distance  $r$  in sphere diameters from the centre of an average sphere.

## GEOLOGY

## Interpretation of Geological Features on a Satellite Photograph

DURING examination of automatic picture transmission system photographs taken by *Nimbus 1*, a photograph exposed from 308 miles above Lake Ontario, during orbit 254, on September 14, 1964, clearly showed the complex folded pattern of the Appalachian Mountains in the Pennsylvania region. The photograph, produced by a slow scan kinescope method, designed and developed by the National Research Council of Canada, specifically to record and reproduce the full capabilities of the 800-line high-resolution automatic picture transmission vidicon of this American meteorological satellite, was one of many received at Ottawa and Frobisher Bay ground stations.

Detailed examination of the photographic pattern as to size, shape and tone of these Appalachian features showed close correlation with the rock-type units as depicted by the 1/250,000 Geologic Map of Pennsylvania, published by the State Geological Survey, 1960. By projecting a photographically reduced map (Fig. 1) on to the photograph (Fig. 2), variations in tonal pattern agreed in fine detail with the rock groups. The rock groups which were predominantly shales showed in light tones, sandstones and conglomerates were dark, and the boundaries of each distinctive group were clearly delineated on the photograph.

The well-known Pennsylvania anthracite coal region in the Wilkes-Barre-Scranton area is a good example. On the map this area is shown as a crescent-shaped rock group, 50 x 8 miles in extent, known as the Post-Pottsville formation (No. 2 of Fig. 1). It consists of brown or grey sandstone and shales with some conglomerate and numerous minable coals. This group is completely ringed by a border, about 2 miles wide, of the Pocono group (No. 1 of Fig. 1), a predominantly grey massive cross-bedded conglomerate and sandstone with some shale. On the photograph we find an exact duplication in shape and size, a crescent light-toned area for the Post-Pottsville

Group (No. 2 of Fig. 2) bordered by a dark-toned strip corresponding to the Pocono Group (No. 1 of Fig. 2) in spite of the fact that this area is shown on a land-use map as forest-covered.

Again, in the Great Valley running through Harrisburg, we find the Martinsburg Formation (No. 3 of Fig. 1) comprising grey to dark grey, light grey to olive weathering shale with interbedded sandstone appearing on the photograph in a light tone (No. 3 of Fig. 2), corresponding in shape and size to that formation on the map. Along the northern edge is a narrow 1-2 mile wide border of Shawangunk Formation (No. 4 of Fig. 1), a grey to tan thick bedded impure quartzite sandstone conglomerate with interbed of shale. This border is duplicated on the photograph as a narrow dark-toned strip of shape and extent corresponding to the formation. Other strips of this formation occur to the north and west, and also appear on the photograph (No. 4 of Fig. 2). Along the southern edge of the Martinsburg Formation, west of the Susquehanna River, is the Beekmantown Group (No. 5 of Fig. 1) of white to grey medium thick-bedded fine-grained quartzite sandstone conglomerate showing on the photograph as a dark-toned area (No. 5 of Fig. 2). East of the Schuylkill River, the southern border is Pre-Cambrian granite gneiss (No. 9 of Fig. 1). On the photograph its identical pattern is repeated in dark tone (No. 9 of Fig. 2). Similar correlation is repeated across the map area with the various geological groups (Nos. 1-12 of Fig. 1) closely delineated on the photograph by corresponding tonal patterns (Nos. 1-12 of Fig. 2).

It is appreciated that the tonal variations can be linked to the forest cover, and forest boundaries are also known to mark changes in geological formations, particularly as is evidenced to the north-east in the Adirondack Mountain area. However, in the Pennsylvania area, forest cover alone is not sufficient to account for the very distinct and uninterrupted sizes and shapes of the tonal pattern that relate to the rock group areas on the map. Large portions of these individual group areas are known to be under intense varying cultivation, with other areas of considerable magnitude given over to industrial com-

plexes and large urban developments. These, of course, influence but do not upset or disrupt the shapes, sizes or tones of the geological patterns seen on the satellite photograph.

This particular photograph is not a peculiar freak of lighting, camera position, etc., for the same features are also reproduced in an earlier *Nimbus* automatic picture transmission, from orbit 137, taken on September 6. On it, the same features appear in similar shapes, sizes and tones as on the photograph taken eight days later, but they are not so easily seen due to the presence of haze and some cloud over the area.

It is therefore felt that the variations of tones shown in this study are specifically related to the rock types of a detailed geological map, and are greatly influenced by the different reflectivity of the various basic rock-soil textures. Further, it would appear that these textures have a greater influence on the tonal rendition in a very high altitude photograph than when their pattern is cluttered with identifiable and directly visible features such as vegetation and man's developments of the Earth's surface—as is the case with conventional aerial photography.

Additionally, it has also been noted in the original photograph that a faint line runs in a slight arc across the picture from where the Susquehanna River enters the

Appalachian Mountains to Chautauqua Lake, which is barely visible through thin cumulus cloud along the south shore of Lake Erie. This linear may possibly be explained by a deep-seated crustal disturbance, such as a buried 'graben' suggested in this area by Prof. J. Tuzo Wilson<sup>1</sup>.

### Eocene-Oligocene Boundary in New Zealand

THE planktonic foraminifera *Hanikoenina*, *Globigeropsis* and *Pseudohastigerina micra* are widely distributed throughout the world and their last appearance has generally been considered to mark the top of the Eocene<sup>1-3</sup>. Hornibrook stated that *H. alabamensis*, *G. index* and *P. micra* make their last appearance in the Runangan Stage, and consequently regarded the Runangan-Whaingaroan boundary as the Eocene-Oligocene boundary in New Zealand<sup>4</sup>.

Blow and Banner gave ranges of planktonic species in the Lindi area of Tanganyika and showed that the genera *Hanikoenina* and *Globigeropsis* make their last appearance

well below the top of the Eocene, the Eocene-Oligocene boundary there being based on the ranges of larger foraminifera<sup>1</sup>. The larger foraminifera of this age do not occur in New Zealand, but from the ranges of planktonic species given by Blow and Banner, Jenkins concluded that the extinction of *Hanikenina* and *Globigerapsis* does not mark the end of the Eocene in New Zealand and that the Eocene-Oligocene boundary lies within the Whaingaroan stage<sup>2</sup>, which contains most of the 'Oligocene' species mentioned by Blow and Banner.

Finlay and Marwick defined the top of the Runangan Stage at the type locality on the west coast of the South Island as marked by the last appearance of *G. index*<sup>3</sup>. I have found that the last appearance of *G. index* there coincides with that of *Globigerina linaperta* and *G. pseudocampliapertura*, and that *G. euapertura* and *G. ampliapertura* make their first appearance immediately above, at the base of the Whaingaroan stage. *H. alabamensis* extends only up to the lower part of the Runangan and this is consistent with its range at Oamaru on the east coast of the South Island (Hornibrook, personal communication). On the other hand, *P. micra* extends up to about the middle of the Whaingaroan stage.

		<i>Buccella</i>	+		
		<i>Cheloniceras</i>			
		<i>Pseudohoplites</i>			
		<i>Globorotalia centralis</i>			
		<i>Cheloniceras</i>			
		<i>G. pseudocampliapertura</i>			
		<i>G. ampliapertura</i>			
		<i>G. euapertura</i>			

Fig. 1. Chart comparing the stratigraphic ranges of some of the Upper Eocene-Lower Oligocene planktonic Foraminifera in New Zealand and the Lindi area of Tanganyika. Arrows indicate greater range than shown on the diagram

The stratigraphic ranges of the significant planktonic species common to New Zealand and the Lindi area are compared in Fig. 1. The only range which is markedly inconsistent is that of the genus *Globigerapsis*, which makes its last appearance earlier than *H. alabamensis* and *Globorotalia centralis* in the Lindi area but later than *H. alabamensis* and *G. centralis* in New Zealand.

Consequently *Globigerapsis* must be regarded as unreliable for correlation between the Lindi area and New Zealand, and from the other planktonic species the Runangan-Whaingaroan boundary appears to be equivalent to the Eocene-Oligocene boundary as delineated by Blow and Banner.

I thank Dr. Paul Vella and Prof. H. W. Wellman for their advice.

## CHEMISTRY

### Photochemical Degradation of Paraquat

THE establishment of world-wide and varied uses of 'Gramoxone'<sup>1</sup> herbicide requires a complete understanding of the behaviour of its active constituent, paraquat, in all circumstances. The present report is concerned with the photochemical degradation of the chemical.

When paraquat dichloride (I) in aqueous solution is irradiated with ultra-violet light in the presence of oxygen, rapid decomposition occurs. The reaction has been conveniently examined on a small scale (10-20 ml.) by stirring a 0.1 per cent aqueous solution of <sup>14</sup>C-methyl paraquat dichloride with a magnetic stirrer in a beaker covered with a sheet of quartz glass and shining a Hanovia model 18 lamp (used without a filter) on it. Fifty micro-litre aliquots were removed at intervals and applied as spots at the top of a strip of chromatography paper, which was afterwards developed using a mixture of *n*-butanol, acetic acid and water (4:1:2). An autoradiograph (Fig. 1) of the resulting chromatograph (prepared by exposing the chromatograph to X-ray film) showed that only two major radioactive decomposition products were formed.

Compound A in Fig. 1 is paraquat itself (shown by comparison of its *R<sub>F</sub>* value with that of an authentic specimen, and by the grey colour it produced when sprayed with potassium iodoplatinate<sup>2</sup>). After three days' irradiation with ultra-violet light, no paraquat remained. The concentration of compound B increased to a maximum after irradiation for 1 day, but itself decomposed until eventually only compound C remained.

Compound B quenched the induced fluorescence of the paper when the chromatograph was observed under ultra-violet light (whereas compound C did not): this provided a useful means of studying the formation of the compound when non-radioactive paraquat was used. Paper chromatography of an irradiated solution on a larger scale yielded sufficient compound B for measurement of its ultra-violet spectrum. In aqueous solution, this showed maximum absorption at 285 mμ; when the solution was acidified, the absorption band underwent a bathochromic shift. A large-scale reaction was performed so that sufficient compound B could be isolated for its identification. One litre of 0.1 per cent aqueous paraquat was irradiated using a Hanovia 10L photochemical

Fig. 1. Autoradiograph of chromatograph of ultra-violet-irradiated <sup>14</sup>C-methyl paraquat

reactor with quartz down-tube which contained a medium pressure mercury vapour arc tube. Oxygen was passed through the irradiated solution, and irradiation was continued until more than 95 per cent of the paraquat had decomposed (judged by paper chromatography of aliquots). This occurred after 4 days and the resulting solution was passed through a column of 'Dowex 50W-X8' cation-exchange resin. Compound *B* was eluted from the column with 2 per cent formic acid (its elution was followed by observing the ultra-violet absorption of the eluate at 270 mμ). Removal of the solvent gave a white solid, which was crystallized from ethanol.

The nuclear magnetic resonance spectrum of the compound was consistent with a methyl quaternary pyridinium compound substituted at the 4-position ( $\delta = 4.43$  (3 protons); 8.13, 8.23 (2 protons); 8.74, 8.85 (2 protons)), and elemental analysis and comparison of its infra-red and ultra-violet spectra with those of an authentic sample showed that the compound was the *N*-methyl betaine of isonicotinic acid (III). The bathochromic shift in the ultra-violet spectrum of III on acidification has been noted before<sup>3</sup>. Compound *B* also had the same *R<sub>F</sub>* value as authentic III on paper chromatography in three solvent systems (4:1:2 *n*-butanol, acetic acid and water; 8:3:4 *n*-butanol, formic acid and water; and 4:1 isopropanol and water).

Ultra-violet irradiation of paraquat labelled with carbon-14 in the  $\alpha$ - and  $\beta$ -positions of the pyridine rings followed by paper chromatography showed that only one major radioactive compound was formed, namely, compound *B*. Thus compound *C* must have been formed from the methyl group of paraquat, and could not have contained any carbon atoms originating from the  $\alpha$ - and  $\beta$ -positions of the pyridine rings.

Fig. 2

When the hydrochloride of the *N*-<sup>14</sup>C-methyl betaine of isonicotinic acid in aqueous solution was irradiated with ultra-violet light it decomposed to yield compound *C* as the only isolable radioactive product. This reaction was repeated on a large scale using non-radioactive methyl quaternary isonicotinic acid, and the solution was irradiated until no starting material remained. Removal of solvent yielded compound *C* and comparison of its infra-red spectrum with that of an authentic sample showed it to be methylamine hydrochloride (IV). This was confirmed by examination of its paper chromatographic behaviour in the three solvent systems already described here.

Carbonyl compounds are probably formed as transitory intermediates in the decomposition since addition of 2,4-dinitrophenylhydrazine to an irradiated solution precipitated a small amount of an orange derivative. Thin-layer chromatography on silica gel showed that this was a mixture of at least six components.

A likely early intermediate is the unsaturated amino-aldehyde II (similar compounds have been obtained from

the reaction of bases with pyridinium compounds<sup>4</sup>), which must be rapidly oxidized. The fragments resulting from this oxidation or a similar one include carbon dioxide, since <sup>14</sup>CO<sub>2</sub> is evolved from paraquat labelled with carbon-14 in the  $\alpha$ - and  $\beta$ -positions of the pyridine rings. When aqueous paraquat is irradiated with ultra-violet light in the absence of oxygen, it decomposes, but compounds III and IV are not formed. Instead, a brown resin, presumably polymeric, remains when all the paraquat has decomposed and the solution is evaporated to dryness. This could result from polymerization of compound II or similar materials.

The same decomposition products (III and IV) are formed when paraquat adsorbed on filter paper or thin layers of silica gel is exposed to ultra-violet light from a mercury vapour lamp, or to sunlight. This decomposition in sunlight seems to occur only when the paraquat is adsorbed on a surface, since paraquat in aqueous solution does not decompose in sunlight to any appreciable extent.

More importantly, paraquat which has been sprayed on plants can be photochemically decomposed on the surface of leaves by sunlight, and compounds III and IV are formed (both of which, incidentally, have very low oral toxicities in mammals). Details of work on the decomposition of paraquat on plants will be published elsewhere.

I thank Dr. J. A. Farrington for assistance in the interpretation of the nuclear magnetic resonance spectrum.

### Autoradiographic Electrophoresis of Tritium-labelled Compounds in a Thin Layer of Buffered Photographic Gelatine

GEL electrophoresis allows the detection of radioactive compounds by contact with a photographic film. I have tried to separate radioactive ions by electrophoresis, using a thin layer of radiosensitive photographic gelatin as supporting medium. I hoped thus to locate smaller amounts of radioactive substances within a shorter time and, above all, to achieve higher efficiency in detection and location of tritium-labelled molecules through autoradiography. This communication gives a brief account of the first runs of autoradiographic electrophoresis in a thin layer of buffered photographic gelatine and affords a glimpse of the possibilities of this new type of supporting medium.

A strip of double-lead 'Kodirex' X-ray film, 10-15 cm long and of the proper width, is immersed for about 20 min at room temperature in a suitable buffer, then quickly blotted between two sheets of filter paper. The film strip is laid on a glass plate on which it sticks tightly. The sample (1-5 μl.) is directly applied on the gelatine layer, without scratching the damp surface. The glass plate used as a support is set on the cover of a Petri dish full of crushed ice, in the central compartment of an electrophoresis apparatus. Two filter-paper wicks, soaked with buffer, ensure the electric junction between the upper surface of the ends of the film and the compartment next to the electrode chambers. A similar glass plate is set on top of the whole system, as a means of reducing evaporation; its weight ensures adequate electric connexion between the filter paper and the gelatine; the thickness of the wicks prevents any contact between the

photographic emulsion and the glass plate used as a cover. When the separation process lasts more than 1 h, evaporation is prevented by the use of another system: the strip is sandwiched between two cooled glass plates, so that the upper glass plate supporting a second cooling Petri dish comes into close contact with the film.

The electrophoresis is carried out at potential gradients of 15–30 V/cm applied for 10 min to 1 h, as the case may be. The film strip is quickly dried in a stream of warm air and stored in the dark until its development through the usual processing.

The entire experiment is carried out in the dark room, with the help of properly filtered light.

(A) *Electrophoretic migrations.* (1) The first runs dealt with the electrophoretic migration, at pH 7.25 (tris/HCl buffer, 0.01 M, containing 5 per cent of glycerol as a means to reduce evaporation), of various substances alone or mixed together: sulphate and taurine-<sup>35</sup>S, taurocholate-<sup>14</sup>C, tritiated succinic acid, a strongly radiolysed tritiated methionine, etc. Fig. 1a shows that one can thus separate and detect histidine-<sup>14</sup>C, glutamic acid-<sup>14</sup>C and tritiated valine from a given mixture of these three amino-acids. The same can be carried out with a mixture of sulphate, cysteine acid and taurine-<sup>35</sup>S. Adsorption is definitely negligible, separation quite sharp, diffusion is weak and, unless the studied compounds' specific activities are very high, radioactive ions have no time to leave any track as they move in the photographic gelatine.

(2) The electrophoretic separation of the three above-named amino-acids was also achieved at pH 5.25 using a volatile buffer (acetic acid/pyridine/water 20/9.5/970 (v/v) containing 5 per cent of glycerol) (Fig. 1b).

(B) *Non-electrophoretic migrations.* The importance of phenomena due to electro-osmosis and evaporation was assessed with the help of a non-ionized compound: *D*-glucose-<sup>14</sup>C solution was regularly applied in small drops 1 cm apart all along the film strip and 17 V/cm potential gradient applied for 1 h. The tracks of Fig. 2 show that at pH 7.25 the radioactive molecules have not been moving except for radial diffusion. Similar results were found at pH 5.25 (pyridine/acetic acid buffer).

(C) *Sensitivity of the method.* Radioactive compounds being in close contact with the silver bromide grains

Fig. 3. Autoradiographic electrophoresis of a strongly tritium-labelled methionine: radiolysis and tracks due to high activity of the substance (tris/HCl buffer, 0.01 M; 5% glycerol) 25 V/cm for 60 min

within the very photographic gelatine layer in which they have been moving, this technique offers a high degree of sensitivity as is shown by the shortness of required exposure and especially by the ability of detecting tritiated substances. Thus, nothing came out of a contact autoradiography between a 'Kodirex' X-ray film and a paper electrophoregram supporting tritiated methionine, whereas in the case of a direct autoradiographic electrophoresis and with ten times less tritiated methionine, a definite darkening was achieved after exposure for 2 days. The method allows the detection of 0.001  $\mu$ c. of tritiated valine after exposure for 6 days.

This technique gives quick detection of ionized radioactive impurities in the course of preparing or storing labelled molecules, especially when they have been tritiated. Fig. 3, for example, shows the result of the autoradiographic electrophoresis of a strongly tritiated methionine, which had undergone radiolysis within the course of storage for three years.

The use, as supporting medium for autoradiographic electrophoresis, of glass plates coated with a thin layer of buffered nuclear emulsion should allow, after development, the microscopic detection of the silver grains or the individual tracks left by the radioactive ions after their migration. A still higher degree of sensitivity would thus be achieved.

Autoradiographic electrophoresis offers an opportunity of estimating by densitometry or grain count the relative amounts of tritium in the ionized compounds of a mixture.

I thank Dr. P. Fromageot of the Department of Biologie, Commissariat à l'Énergie Atomique, Saclay, for his advice.

### Nitrous Oxide as a Scavenger in the Radiolysis of Water

NITROUS oxide has been widely used as a specific scavenger for the solvated electron in the radiolysis of liquid water<sup>1-3</sup>; the rate constant for reaction (1) being greater than that for reaction (2) by a factor of 10<sup>3</sup> or more:

Fig. 1. Separation of histidine-<sup>14</sup>C, H<sup>3</sup>-valine and glutamic acid-<sup>14</sup>C (a), at pH 7.25 (tris/HCl buffer 0.01 M; 5% glycerol), 20 V/cm for 45 min; (b), at pH 5.25 (pyridine/acetic acid/water buffer, 5% glycerol), 20 V/cm for 60 min. The application points are indicated by an arrow

Fig. 2. Glucose-<sup>14</sup>C deposits 1 cm apart; 17 V/cm for 60 min. The radioactive glucose has radially diffused, but there is no non-electrophoretic migration

$\text{N}_2\text{O}$  concentrations  $> 1.2 \times 10^{-3} \text{ M}$  have invariably been found necessary to obtain values of  $G(\text{N}_2)$  independent of  $[\text{N}_2\text{O}]$  despite the large magnitude of  $k_1$ . Values of  $G(\text{N}_2) = 3.0 \pm 0.1$  obtained with this high concentration of  $\text{N}_2\text{O}$  have been equated to  $G(e_{aq}^-)$ .

Using an experimental technique similar to that reported previously<sup>1</sup>, we have examined the variation of  $G(\text{N}_2)$  as a function of  $[\text{N}_2\text{O}]$  in pure water at natural pH irradiated with cobalt-60  $\gamma$ -rays. Contrary to the findings of Dainton and Peterson<sup>1</sup>, who used larger doses, we obtained the results shown in Fig. 1 for doses of  $7 \times 10^{17} \text{ eV ml}^{-1}$ . The curve for  $G(\text{N}_2)$  consists of two distinct steps: first, a very rapid increase in  $G(\text{N}_2)$  from 0 to  $2.45 \pm 0.1$  with increasing  $[\text{N}_2\text{O}]$  from 0 to  $4 \times 10^{-3} \text{ M}$ ; secondly, a slow increase from  $2.45$  to  $3.1 \pm 0.1$  with increasing  $[\text{N}_2\text{O}]$  from  $4 \times 10^{-3}$  to  $1.2 \times 10^{-2} \text{ M}$ , above which  $G(\text{N}_2)$  was independent of  $[\text{N}_2\text{O}]$  up to  $2.5 \times 10^{-2} \text{ M}$ . Values of  $G(\text{N}_2) < 2.45$  were obtained at  $[\text{N}_2\text{O}] < 4 \times 10^{-3} \text{ M}$  but these are not shown in Fig. 1 because with a total dose of  $7 \times 10^{17} \text{ eV ml}^{-1}$  depletion of  $\text{N}_2\text{O}$  occurred. However, we have shown at smaller doses, where very similar curves to that given in Fig. 1 are obtained, that  $G(\text{N}_2) = 1.9$  at  $2 \times 10^{-3} \text{ M N}_2\text{O}$ .

We interpret this curve as indicating that the very efficient scavenging step represents reaction (1) and hence that  $G(\text{N}_2) = 2.45 \pm 0.1 = G(e_{aq}^-)$ . This is more in accord with the values of  $G(e_{aq}^-)$  obtained using other techniques than is the value of  $3.1 \pm 0.1$  found at  $1.2 \times 10^{-2} \text{ M}$ . The efficient scavenging by  $4 \times 10^{-3} \text{ M N}_2\text{O}$ , when competing for  $e_{aq}^-$  with radiation products only is also more consistent with the high value of  $k_1 = 0.86 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$  (ref. 4).

The second step in the curve seems to be the scavenging by  $\text{N}_2\text{O}$  of a second radiation produced species, rather than a consequence of a back reaction or intra-spur scavenging of  $e_{aq}^-$ , because the plot of  $\{G(\text{N}_2) - G(e_{aq}^-)\}^{-1}$  versus  $[\text{N}_2\text{O}]^{-1}$  is linear. The identity of this species having a yield of  $0.65 \pm 0.1$  is at present uncertain but it may be equivalent to the hydrogen atom or to the entity designated  $\text{H}_2$  by Dainton and Peterson<sup>1</sup>. The increase in  $G(\text{N}_2)$  at  $(0.4 \text{ to } 1) \times 10^{-3} \text{ M N}_2\text{O}$  cannot be attributed to intra-spur scavenging of  $e_{aq}^-$  because no region where  $G(\text{N}_2)$  was independent of  $[\text{N}_2\text{O}]$  was observed and at  $10^{-4} \text{ M N}_2\text{O}$  where the second step was  $> 30$  per cent complete the lifetime of  $e_{aq}^-$  would need to be an order of magnitude longer than the  $10^{-7} \text{ sec}$  predicted for intra-spur processes to be completed. Furthermore, although  $G(\text{H}_2)$  falls from  $0.5$  to  $0.1$  due to the addition of  $4 \times 10^{-3} \text{ M N}_2\text{O}$ , further addition of  $\text{N}_2\text{O}$ , up to  $2.5 \times 10^{-2} \text{ M}$ , does not affect  $G(\text{H}_2) = 0.1$ , so that the species scavenged by  $\text{N}_2\text{O}$  in the slower step does not normally lead to the formation of  $\text{H}_2$ . It can be noted also that, bearing in mind the possible alternative reactions of this species, the  $1.2 \times 10^{-2} \text{ M N}_2\text{O}$  necessary to scavenge it

completely is consistent with its rate constant for reaction with  $\text{N}_2\text{O}$  being  $10^4\text{--}10^7 \text{ M}^{-1} \text{ s}^{-1}$ , the probable order of magnitude of  $k_2$  (ref. 2).

Fig. 1 also indicates that  $G(\text{H}_2) + G(\text{O}_2)$  is constant at  $\sim 0.5$  over the full range of  $[\text{N}_2\text{O}]$ . In fact,  $G(\text{O}_2)$  increases as  $G(\text{H}_2)$  falls and both processes are markedly dependent on dose in contrast to the yields of  $G(\text{N}_2)$ . This dose dependence and certain competition investigations will be discussed elsewhere. Values of  $G(\text{N}_2)$  shown in Fig. 1 were corrected for small 'background' yields of  $\text{N}_2$ . Plots of  $G(\text{N}_2)$  versus dose showed positive intercepts as others have reported<sup>1,2</sup>. We attribute these to the fact that when added to an apparently thoroughly de-aerated sample of water (de-aerated by freezing-pumping-thawing cycles or by boiling and pumping)  $\text{N}_2\text{O}$  is able to release traces of dissolved nitrogen (and probably oxygen) from the liquid—amounts up to  $0.2 \mu\text{moles}$  from  $25 \text{ ml.}$  of water, depending on the  $\text{N}_2\text{O}$  pressure.

We thank Dr. H. F. Batho and his staff of the British Columbia Cancer Institute for their assistance in performing the irradiations. This work was supported by the National Research Council of Canada.

## Spectroscopic Evidence of Chemical Interactions at the Gold Film-Silica Substrate Interface

CERTAIN 'intermediates', when placed between a substrate and an evaporated gold film, promote adhesion between the film and the substrate<sup>1</sup>. As a preliminary part of a systematic study of the nature of the chemical interactions in such systems, it was necessary to examine the effect of varying the temperature of the substrate during deposition of gold in the absence of intermediates. The interactions at the ceramic substrate-gold interface were examined with the potassium bromide pellet infrared spectroscopy technique.

Silica powder ('Cabosil') was heated at different temperatures up to  $1,100^\circ \text{C}$  on a tantalum heater strip within an evaporation vessel at a pressure of  $10^{-4}\text{--}10^{-5}$  torr. The amount of powder used was approximately  $3 \text{ mg.}$  and it was maintained at a given temperature for  $10 \text{ min.}$  before evaporation of the gold at that temperature. The sample was allowed to cool in vacuum, then thoroughly mixed with potassium bromide (spectroscopic grade), and pressed at  $80,000 \text{ lb./in.}^2$  to yield a pellet containing  $0.25 \text{ mg.}$  of the silica per  $400 \text{ mg.}$  of potassium bromide. The potassium powder was stored in an oven at  $50^\circ \text{C}$  and the pellets stored in a vacuum desiccator at room temperature before scanning.

The thickness of the deposited layer, calculated from the cosine distribution equation and verified gravimetrically, was approximately  $150 \text{ \AA.}$  At temperatures above  $900^\circ \text{C}$ , the high rate of re-evaporation of gold from the surface and the high partial pressure of gold at such temperatures close to the melting point of gold ( $1,083^\circ \text{C}$ ) introduced additional complicating factors which will be considered in later reports. The temperature of the exposed surface of the powder was measured with a chromel-alumel thermocouple to a precision of  $\pm 3$  per cent at all temperatures.

The pellets were scanned using a Beckman IR-4 spectrophotometer in the range  $1\text{--}16 \mu$ . The reproducibility of scans of different samples of the same system was approximately  $1\text{--}2$  per cent (transmittance) throughout most of the  $1\text{--}16 \mu$  range.

Fig. 1. Variation of  $\Delta G(\text{N}_2)$  and  $\bigcirc G(\text{N}_2) + G(\text{H}_2) + G(\text{O}_2)$  with  $\text{N}_2\text{O}$  concentration. Total dose in each experiment =  $7 \times 10^{17} \text{ eV ml}^{-1}$ .

Silica powder ('Cabosil') exhibits absorption bands at 8.86, 12.12, and 14.15  $\mu$  (ref. 2). Other weaker bands at about 2.8 and 6.1  $\mu$  correspond to the —OH vibrations of the silanol surface groups or to the different forms of water associated with the silica powder\*. We have found that the evaporation of gold on to silica at room temperature increases the transmittance of the 'flat regions' at the sides of the band, thus improving the sharpness of all three absorption bands.

Fig. 1 presents the transmittance spectra between 6.0 and 13.0  $\mu$  of pure silica powder that had been heat-treated at different temperatures and made into pellets about 2 h after the heat treatment. The spectra corresponding to the different samples superimpose, and no distortion of the band is apparent. The spectra of silica powder in Fig. 2 are for samples which were subjected to identical heat treatment procedures and were held at the heat treatment temperature while being plated with gold. The potassium bromide pellets were made about 2 h after the gold deposition.

In Fig. 3 are shown the spectra for the same silica powder as in Fig. 2, with the exception that the potassium bromide pellets were made about a week after the gold evaporation. The spectra of the different samples fall right on top of each other once again.

The decrease in transmittance at the short-wave-length side of the 8.86  $\mu$  band with increase in temperature of the silica during gold deposition (Fig. 2) was also observed to

Fig. 3. Infra-red spectra of the same silica samples as in Fig. 2, but scanned one week after the heat treatment-gold filming operations. Heat-treatment: —, 25° C; ---, 500° C; — · —, 800° C; — — —, 1,000° C.

occur when certain metals were evaporated on to the silica substrate at room temperature. However, the spectra corresponding to these metal-silica systems did not change with time. In contrast, it is apparent from Fig. 3 that for silica-gold the effect causing the decrease in transmittance with increasing temperature is reversible.

'Intermediates' such as germanium, bismuth and chromium in the form of the oxide have been found to increase the adherence of gold films to a silica substrate. If we postulate that excitation of the silicon-oxygen energy-levels is related to bonding at the silica-metal interface then the excitation caused by the pure gold when deposited at high substrate temperatures would indicate, by analogy, formation of an oxygen-gold bond at the silica-gold interface. The formation of a surface gold oxide at high temperatures has been suggested previously<sup>4</sup>. The oxide when formed was found to decompose rapidly. This is corroborated by the present results where the instability of the surface gold oxide could account for the de-excitation with time shown in Fig. 3.

The reversibility of the proposed formation of the surface gold oxide may be expressed in equivalent form as either the oxide is unstable or that the silicon-oxygen-water interaction is energetically more stable than silicon-oxygen-gold.

For the purpose of this preliminary analysis, we can assume that the vibrations of the silicon-oxygen group are approximated by those of an anharmonic oscillator<sup>5</sup>. In the absence of rotational interactions, the broadening of a fundamental infra-red absorption band may be attributed to a delocalization of either the ground-state-level or of higher levels or a combined delocalization of both. In liquids, for example, Brownian motion may delocalize the ground state to cause symmetrical broadening<sup>6</sup>.

For the present system, we may postulate that the interaction between gold atoms and silicon-oxygen surface sites at high temperatures produces, on cooling to room temperature, a delocalization of the silicon-oxygen vibrational levels. This could either be in the form of a lowering of the ground-state-level or of a lowering of all levels. In either case, the delocalization will result in a broadening of only the short-wave-length side of the absorption band, as in fact is observed (Fig. 2). Since the silicon-oxygen-gold interaction is unstable, relaxation of the delocalized levels occurs with time. Apparently, for the interaction with other metals such as bismuth the delocalization is stable, indicating strong bonding to the silicon-oxygen surface sites.

Further research is in progress to clarify the details of the probable formation of surface gold oxide and to quantify the interactions of silica surfaces with gold and other metals.

### $\alpha$ -Dehydro Dimer—a Major Product in Irradiated Methyl Laurate

DURING investigations of the effect of radiation on lipid components of food we have examined the effect of  $\gamma$ -radiation on methyl laurate. There is little information in the literature on the effect of  $\gamma$ -radiation on higher saturated fatty acid esters<sup>1</sup>. Here we report the constitution of the major product in the fractions of higher boiling point than methyl laurate.

The methyl laurate used was Eastman Organic Chemicals practical grade which was further purified by vacuum distillation through a packed column. Only the middle fractions from the distillation were used for irradiations. Using gas chromatography with a flame ionization detector, purity was estimated to be > 99.9 per cent. The methyl laurate was thoroughly degassed and then sealed under vacuum into an all-glass ampoule before irradiation to 40 Mrads with  $\gamma$ -radiation from spent fuel elements. The dose rate was 0.22 Mrads/h, estimated by using the ferrous sulphate dosimeter, taking  $G_{Fe^{+++}} = 15.6$ .

Most of the unchanged methyl laurate from the irradiated material was removed by vacuum distillation, and the residue was fractionated using column chromatography with silica gel as adsorbent, and gradient elution by a petroleum ether-diethyl ether mixture (Fig. 1).

Using gas chromatography, the fractions in peak A (Fig. 1) were found to be almost entirely unchanged

Fig. 1. Column chromatogram of the distillation residue from methyl laurate irradiated to 40 Mrads. Column load, 4.533 g; material recovered, 4.458 g

Fig. 2. Mass spectrum of  $\alpha$ -dodecane 11, 12 dimethyl carboxylate

methyl laurate. The first three fractions in peak B were crystalline, and examination of this material by gas chromatography using a column packed with 1.5 per cent SE. 30 on silanized 'Chromosorb W' indicated that it had one major component. The component was found to be the  $\alpha$ -dehydro dimer,  $\alpha$ -dodecane 11, 12 dimethyl carboxylate (DDMC),  $\text{CH}_3(\text{CH}_2)_9\text{CH}(\text{COOMe})\text{CH}(\text{COOMe})$  ( $\text{CH}_3$ )<sub>2</sub>CH, on the basis of the evidence which follows. After recrystallization from ethyl alcohol, the melting point of the compound was found to be 54°–54.5° C uncorrected. The subsequent fractions contained the compound in diminishing amounts up to fraction 200; these and all other fractions were found to be complex mixtures. Although the retention times of some components were possibly too great to be detected by the gas chromatograph, it can be seen from Fig. 1 that the individual amounts of all other components are likely to be relatively small.

The infra-red spectrum closely resembled that for methyl laurate, showing a strong absorption at 1,737  $\text{cm}^{-1}$  in the ester carbonyl region. The relative intensity of the carbonyl to the  $\text{CH}_2$  absorption in carbon tetrachloride solution was similar to that for methyl laurate. Absorption at 718  $\text{cm}^{-1}$  indicated that the  $(\text{CH}_2)_9$  grouping was present, although the irregular spacing of a series of absorptions in the spectrum of the crystalline material over the region 1,190–1,275  $\text{cm}^{-1}$  suggested that the  $\text{CH}_2$  groups were not in a simple straight chain.

The parent peak in the mass spectrum (Fig. 2) corresponded to a molecular weight of 426, which suggested that it was a dehydro dimer of methyl laurate (mol. wt. = 214). The absence of peaks at  $M-73$  (loss of  $\text{CH}_3\text{COOCH}_2$ ),  $M-105$  (loss of  $\text{CH}_3\text{COOCH}_2 + \text{OCH}_2 + 2\text{H}$ ), which are characteristic peaks in the mass spectrum of methyl esters of normal chain dibasic acids<sup>2</sup>, indicated that no  $\alpha$ -OH<sub>2</sub> groups were present and therefore both methyl laurate moieties were linked at the  $\alpha$  position. Further evidence for this structure was the presence of strong peaks at  $M/e = 213$  and 214, and peaks at  $M/e = 286$  and 170, all of which corresponded with those reported by Harrison *et al.*<sup>3</sup> for the related compound which they synthesized, the  $\alpha$ -linked dehydro dimer of methyl stearate.

The nuclear magnetic resonance spectrum of the compound (Fig. 3) gave further evidence that the linkage was between the  $\alpha$ -carbon atoms. The hydrogen atoms attached to the  $\alpha$ -carbon atom in methyl laurate gave a triplet as expected, with a chemical shift,  $\delta = 2.3$  p.p.m. approximately and  $J = 6$  c.p.s. approximately; the ratio from the integral of the absorption due to the chain methylene groups to that due to the  $\alpha$ -hydrogens was 8.5:1, in good agreement with the expected ratio of 9:1. Absorption attributable to an  $\alpha$ -CH<sub>2</sub> grouping was absent from the spectrum of the crystalline compound, but an unresolved multiplet centred at  $\delta = 2.64$  p.p.m. is consistent with an  $\alpha$ -methine grouping, linked

Fig. 3. Nuclear magnetic resonance spectrum of methyl laurate (curve A) and *n*-docosane 11, 12 dimethyl carboxylate (curve B). Solvent, deuterated chloroform.

as in DDMC. The additional complexity of the  $\alpha$ -proton signals was expected because of the coupling of the methine protons with each other as well as with the  $\beta$ -methylene groups. The shift downfield was due to the influence of a second carbonyl group, together with the usual downfield displacement of methine protons versus methylene protons. The ratio of the intensity of this band to that of the chain methylene groups was approximately 1:20, in reasonable agreement with the expected ratio of 1:18.

The *G*-value for the formation of DDMC from methyl laurate was estimated at 0.19 using gas chromatography to determine the proportion of this compound present in the fractions constituting peak B, Fig. 1. The gas chromatogram of the distillation residue from methyl laurate irradiated to 5 Mrads reveals that DDMC is still the major reaction product.

We thank Dr. A. Robertson of the Chemistry Department of the University of Sydney for providing the nuclear magnetic resonance data, and Dr. K. E. Murray for helpful advice and for recording the mass spectrum.

## BIOCHEMISTRY

### Identification and Estimation of Tocotrienols in Hevea Latex

THE four tocotrienols related to  $\alpha$ -,  $\beta$ -,  $\gamma$ - and  $\delta$ -tocopherols have been reported to be present in palm oil<sup>1</sup> (Table 1). Some of these compounds are not distributed widely; in fact, palm oil has hitherto been the only known

Table 1

source of  $\delta$ -tocotrienol. This communication reports the presence in a sample of latex from the rubber tree, *Hevea brasiliensis*, of a surprisingly large amount of free and esterified  $\alpha$ -,  $\gamma$ - and  $\delta$ -tocotrienols together with a much smaller amount of  $\alpha$ -tocopherol.

Concentrated latex containing about 60 per cent of rubber and stabilized with ammonia was kindly provided by the Natural Rubber Producers Research Association through Dr. E. G. Cookbain. The latex was extracted by the Folch method<sup>2</sup>, giving 1-1.2 per cent of an oily, slightly yellow lipid mixture. An extract from 20 g of latex was chromatographed on a column of alumina (acid-washed and weakened to Brockmann Grade 3) and fractions eluted by ether/light petroleum mixtures were collected. The 2 per cent (v/v) ether in light petroleum (*E/P*) fraction had an ultra-violet absorption spectrum closely resembling that of  $\alpha$ -tocopheryl acetate (Fig. 1), while the spectra of the 4 per cent and 10 per cent *E/P* fractions indicated the presence of free tocopherol (Fig. 2). The 4 per cent *E/P* fraction showed an absorption maximum of 298 m $\mu$  and an inflexion at 292 m $\mu$  (in cyclohexane) similar to the spectrum of  $\alpha$ -tocopherol, and the 10 per cent *E/P* fraction had peaks at 296 m $\mu$  and 301 m $\mu$  and so resembled both  $\gamma$ - and  $\delta$ -tocopherol.

Thin-layer chromatography of the 4 per cent and 10 per cent fractions by the two-dimensional method of Pennock, Hemming and Kerr<sup>3</sup> showed four tocopherols to be

Fig. 1. Ultra-violet absorption of tocopheryl esters. 2 per cent *E/P* fraction—27.7 mg per cent in cyclohexane (—);  $\alpha$ -tocopheryl acetate—81.6 mg per cent in cyclohexane (---).

Fig. 2. Ultra-violet absorption of free tocopherols. 4 per cent E/P fraction—59.6 mg per cent in cyclohexane (—), 10 per cent E/P fraction—74.4 mg per cent in cyclohexane (----).

present. Chromatographic comparisons with authentic tocopherols, together with colours given by diazotized *o*-dianisidine, indicated that  $\alpha$ -,  $\gamma$ - and  $\delta$ -tocotrienols and a little  $\alpha$ -tocopherol were present. Larger amounts of the tocotrienols were obtained by preparative thin-layer chromatography and each substance was hydrogenated in the presence of platinum oxide catalyst. The products had thin-layer chromatographic properties similar to those of  $\alpha$ -,  $\gamma$ - and  $\delta$ -tocopherols.

Portions of the ester fractions were saponified<sup>3</sup> or hydrolysed with acid<sup>4</sup> and the products examined by two-dimensional thin-layer chromatography. After alkaline hydrolysis the main surviving product was  $\gamma$ -tocotrienol with smaller amounts of  $\alpha$ - and  $\delta$ -tocotrienols, while after acid hydrolysis there was more  $\delta$ -tocotrienol and less  $\gamma$ -tocotrienol (Table 2). Two reducing spots with lower  $R_F$  values than  $\delta$ -tocotrienol were evident after acid hydrolysis. Whether these materials, which had ultra-violet absorption spectra resembling those of both  $\gamma$ - and  $\delta$ -tocopherols and gave stains with *o*-dianisidine, were artefacts of acid hydrolysis remains to be decided.

Table 2. TOCOTRIENOLS FROM THE ESTER FRACTION OF LATEX LIPID

Method of hydrolysis	Total tocopherol-like compounds ( $\mu\text{g/g}$ latex)	Tocotrienol	$\mu\text{g/g}$ latex	% Composition
Acid	514*	$\alpha$ -T-3	trace	—
		$\gamma$ -T-3	290	83.3
		$\delta$ -T-3	52	16.7
		$\alpha$ -T-3	13	2.6
Alkali	508†	$\gamma$ -T-3	474	93.2
		$\delta$ -T-3	21	4.2

\* Estimated by Emmerie-Engel colour test.

† Estimated from ultra-violet absorption spectrum based on the  $E_{1\%}^{1\text{cm}}$  of  $\gamma$ -tocopherol (that is, 294 m $\mu$  0.64).

Quantitative determinations were made of free and esterified tocotrienols.  $\alpha$ -Tocopherol was present but in concentrations too low to be measured. Latex (5.6 g) was extracted by the Folch method and the resulting lipid (67 mg) was chromatographed on alumina. The ester fraction, eluted by 2 per cent E/P, was hydrolysed by refluxing with ethanolic sulphuric acid for 3 h (ref. 4). Tocotrienols were estimated by the Emmerie-Engel reaction following two-dimensional thin-layer chromatography according to Whittle<sup>5</sup> (Table 2). Tocotrienols were also obtained from another 2 per cent E/P fraction by alkaline hydrolysis and estimated (Table 2). Neither method of hydrolysis seemed to give full recovery. Free

Table 3. FREE TOCOTRIENOL CONTENT OF LATEX LIPID

Tocotrienol*	$\mu\text{g/gm}$ Latex	% Composition
$\alpha$ -T-3	124	30.9
$\gamma$ -T-3	253	62.9
$\delta$ -T-3	25	6.2

Total reducing substance† 436

\*  $\alpha$ -Tocopherol was also present but only in trace amounts.

† In the 10 per cent E/P fraction.

tocopherols were eluted from the column by 10 per cent E/P and estimated as already mentioned (Table 3).

Thus  $\alpha$ -,  $\gamma$ - and  $\delta$ -tocotrienols occur both free and esterified in the lipid fraction of *Hevea* latex, and together these tocotrienols make up about 8.2 per cent of the lipid or 0.9 per cent of the latex.

Rubber latex is collected from the tree every other day and so synthesis of its components must be quite rapid. If latex were collected from a tree which had not been tapped for some time the tocotrienol/tocopherol pattern might be quite different. It was suggested earlier<sup>1</sup> that tocopherol synthesis could occur by successive methylation of  $\delta$ -tocotrienol followed by hydrogenation of the side-chain. The presence of mono-, di- and tri-methyl tocotrienols and of only the trimethyl tocol ( $\alpha$ -tocopherol) in *Hevea* latex agrees with the scheme.

## Automated Peptide Synthesis

SOLID-PHASE peptide synthesis was conceived and developed with the view of eventually automating the synthesis of polypeptides<sup>1,2</sup>. In principle the process has certain characteristics which lend themselves to mechanization, and by exploitation of these properties an apparatus has now been constructed which performs automatically all the manipulations involved in the synthesis of a polypeptide chain.

Solid-phase peptide synthesis depends on the stepwise assembly of the peptide chain while it is covalently anchored at one end to an insoluble solid particle, followed by liberation of the peptide from the solid support after completion of the synthesis. This technique provides a number of advantages over conventional methods. One important advantage is that the peptide chain, while firmly attached to a totally insoluble particle, can be carried without loss through the many separate steps to which it must be subjected during the synthesis. In addition, the solid support provides important physical properties which greatly simplify the mechanical manipulations involved in mixing, filtering and washing of the peptide. Thus it becomes possible to carry out all the synthetic steps in a single reaction vessel without the need for repeated transfer of material from one container to another, and without the usual losses associated with such manipulations. After any synthetic reaction an effective purification procedure is necessary. Classically this has been recrystallization. In the solid-phase method the purification procedure is simply thorough and efficient washing. Effective washing is readily carried out mechanically while recrystallization is not.

The polypeptide chain has one inherent property which lends itself to automated synthesis—the repeating peptide bond which forms the backbone of the molecule. In principle, the addition of each amino-acid can be done in

exactly the same way. Thus the chain can be assembled in a stepwise manner by a relatively simple series of reactions which is repeated for each peptide bond, using the appropriate amino-acid derivative according to the sequence desired in the peptide.

Utilization of the combined advantages afforded by peptide structure and solid-phase synthesis has led to the construction of the instrument to be described. While the instrument has so far been operated with one particular set of amino-acid derivatives and reaction conditions, it was designed with sufficient flexibility to be adaptable to the use of a wide range of protecting groups and coupling reactions. The apparatus can be divided into two main parts, the first being the reaction vessel with the components required to store and select reagents and to transfer them into and out of the vessel, and the second being the programmer which automatically controls and sequences the operation of the various components.

The reaction vessel is similar to one previously described<sup>1</sup>, but modified to contain a small fritted disk at the top in addition to the large disk at the bottom. Reagents and solvents are stored in suitable reservoirs which are connected by 'Teflon' tubing to a motor-driven 12-port circular 'Teflon' selector valve. The proper solution is then pumped into the bottom of the reaction vessel for a specified time by an all-'Teflon' diaphragm metering pump. Air is displaced at the top through a capillary tube which is then closed by a solenoid-operated valve. The contents of the vessel are mixed by rotation of the vessel through 180° at a rate of 10 cycles per min. After a suitable period the vessel is stopped in a vertical position and the solvent removed by filtration under vacuum through the fritted disk at the bottom, while dry air is admitted at the top. The rotary valve then selects the next reagent or solvent, and the pumping, mixing and filtering steps are repeated. During one complete cycle of the synthesis the rotary valve makes one complete revolution and thus selects in sequence each of the reagents and solvents required for the lengthening of the peptide chain by one amino-acid residue. The correct amino-acid solution for each succeeding cycle is selected by a second rotary valve which advances one position for each cycle of the synthesis.

In order to control these events a stepping-drum programmer is used. Properly positioned pins on the drum activate micro-switches which in turn operate individual components in the apparatus. At the end of each operation the drum is stepped to the next position by a time-controlled signal. The programme can be readily changed by resetting the pins and timers to conform to the conditions required by the particular reactions which are being used for the synthesis.

The apparatus was programmed specifically to carry out the synthesis of peptides using *t*-butoxycarbonyl-amino-acids and the dicyclohexylcarbodiimide-mediated coupling reaction. Under these conditions 80 separate drum steps were needed for the addition of one amino-acid residue to the peptide chain. This cycle was completed in 4 h, after which the programme was automatically repeated in exactly the same way except that a new amino-acid was introduced. In the present model, provision has been made for sequential addition of six amino-acids during a 24-h period without manual attention.

The operation of the instrument thus programmed was tested by repetition of the recent solid-phase synthesis of bradykinin<sup>2</sup>. The reaction vessel was loaded with 10 g of *t*-butoxycarbonyl-nitro-L-arginine-resin. The coupling of the eight additional amino-acids to complete the protected nona-peptide chain of bradykinin on the resin was accomplished in 32 h of continuous operation of the machine. The peptide was cleaved from the resin, hydrogenated, and purified by countercurrent distribution as previously described. The results, based on yield,

purity, and biological activity, were comparable with those obtained by the manual solid-phase synthesis, while the time and effort were significantly reduced. The improvements in overall time and effort are expected to be major benefits when syntheses of long-chain polypeptides are undertaken.

This work was supported in part by U.S. Public Health Service grant A-1260. We thank Dr. D. W. Woolley for his advice, and Mr. Nils Jernberg for the design and construction of the rotary valves.

### Malic Dehydrogenase Isozymes

It has been shown previously<sup>1-3</sup> that at least two isozymes of malic dehydrogenase are present in the extracts of various tissues. In addition, the distinct characteristics of these isozymes have been demonstrated by the recent reports<sup>4-6</sup>.

In 1963 Thorne, Grossman and Kaplan<sup>7</sup>, using electrophoresis on starch gel, separated six fractions from malic dehydrogenase in the pig heart mitochondria. We recently reported<sup>8</sup> that two or more isozymes of malic dehydrogenase in the separable form (NAD, oxidoreductase EC 1.1.1.37) were found in the extracts of rat and human tissues on the cellulose acetate paper according to the method of Barnett<sup>9</sup>. The present investigations are concerned with the separations of malic dehydrogenase isozymes (NAD, NADP, oxidoreductase EC 1.1.1.40) in rat tissues. Rat tissues were homogenized in distilled water, frozen and thawed twice, and then these solutions were cleared by high-speed centrifugation (for 30 min at 15,000g). The separation was electrophoresed on cellulose acetate paper at 4° C. After electrophoresis the resulting papers were incubated with NAD, NADP, phenazine methosulphate, malic acid and nitro blue-tetrazolium or INT (for 10 min at 37° C in the dark). On separation by electrophoresis three bands were obtained, dependent on the presence of the specific substrate. The results obtained with rat tissues are shown in Fig. 1 and Fig. 2. It has been shown that the first and third bands

Fig. 1. Isozyme patterns of malic dehydrogenase (NAD, NADP) in rat tissue extracts: 1, brain; 2, liver; 3, heart; 4, kidney; 5, skeletal muscle; 6, testis.

Fig. 2. Isozyme patterns of malic dehydrogenase (NAD) in rat tissue extracts: 1, brain; 2, liver; 3, heart; 4, kidney; 5, skeletal muscle; 6, testis

were of malic dehydrogenase (NAD) and the second band was of malic dehydrogenase (NADP) enzyme respectively. The former was inhibited completely by the increasing concentration of oxaloacetate, but the latter was not inhibited by oxaloacetate or pyruvate. It was suggested that the latter is malic enzyme established by Ochoa<sup>10,11</sup>. The same number of bands were present in the different extracts. However, the significance of the presence of the isozymes is not known. We are now trying to elucidate the significance of their function.

### Short Pseudo-repeat in Paramyosin

PARAMYOSIN, a fibrous protein which has so far only been found in the muscles of invertebrates, gives an X-ray pattern with sharp 1.5 and 5.1 Å meridional and diffuse 10 Å near-equatorial reflexions and so is classified with α-keratin, myosin and fibrinogen as an α-fibrous protein. The X-ray patterns of these proteins differ, however, in the low-angle region where the pattern may be indexed on a repeat of 198 Å for α-keratin<sup>1</sup>, 420 Å for striated muscle<sup>2</sup>, 226 Å for fibrinogen<sup>3</sup> and 725 Å for paramyosin<sup>4</sup>. The only one of these low-angle patterns which is clearly understood is that of paramyosin which may be interpreted in terms of either the two-dimensional net shown in Fig. 1(a) or a helix<sup>5</sup>. Electron micrographs have shown a two-dimensional pattern of spots<sup>6</sup> similar to the lattice in Fig. 1(a) where the axial repeat is 725 Å, and this is reduced to 145 Å in axial projection (Fig. 1(b)). This communication reports a pseudo-repeat of 29 Å in axial projection which shows up when the paramyosin is treated with silver.

Table 1. INTENSITIES OF MERIDIONAL REFLEXIONS ON X-RAY PATTERNS FROM NATIVE AND SILVER-TREATED PARAMYOSIN

Reflexion (order of 145 Å)	Native	Silver-treated
1	vs	—
2	vs	vs
3	vs	vs
4	m	m
5	ms	vvs
6	s	s
7	ms	m
8	s	s

It is well known that if atoms of high atomic number can be isomorphously incorporated into organic crystals, the positions of these atoms are readily determined by X-ray methods<sup>7,8</sup>, and information can often be obtained about the structure of the rest of the molecule. This technique has been successfully applied in the complete structure determination of globular proteins<sup>9</sup>. In the case of fibrous proteins, metal treatment of collagen<sup>10</sup>, α-keratin<sup>11</sup> and feather keratin<sup>12</sup> leads to changes in the intensities but not the positions of low-angle X-ray reflexions, and this may be taken as an indication that these proteins have taken up metal atoms isomorphously. Although complete structure determination of these fibrous proteins has not been achieved by this method, it is clear that when isomorphous replacement occurs, the possibility of obtaining information about the molecular structure is considerably increased, especially in the case of paramyosin where the low-angle pattern is readily interpreted.

Paramyosin-containing fibres from the Sydney rock oyster (*Crassostrea commercialis*) adductor muscle were dried *in situ* over phosphorus pentoxide and then removed and soaked for four days in a 1 per cent aqueous solution of silver nitrate at room temperature. The fibres were then washed for one day in distilled water, and air-dried. The X-ray diffraction pattern (Fig. 2) was obtained by exposing the fibres for 2 days in a 5-cm microcamera using a lead glass capillary; the camera was evacuated during exposure. In Table 1, the intensities of the low-angle meridional reflexions from the native and the treated fibres are compared. The axial period was the same in both cases and the only striking difference in the relative intensities was the intensification in the silver-treated case of the meridional reflexion corresponding to a spacing of 29 Å which

Fig. 1. (a) Two-dimensional lattice derived from low-angle X-ray pattern of dry native paramyosin.  $a = 250$  Å,  $b = 725$  Å,  $\gamma = 90.5^\circ$ . (b) Axial projection of (a). (c) Axial projection of the distribution of silver atoms in the treated protein

Fig. 2. Low-angle X-ray pattern of silver-treated paramyosin

was one-fifth of the 145 Å projected periodicity in the native material. Since no new reflexions appeared this means that the metal atoms had entered the protein in such a way as to preserve the original lattice and also to show up a pseudo-repeat of 29 Å in axial projection illustrated in Fig. 1(c).

It is difficult to give a precise interpretation of this pseudo-repeat. Periods of 1400 Å have been observed in electron microscopy of reprecipitated fibrils<sup>13</sup> and this has been associated with molecules lying parallel to the fibre axis in the native material and separated by an axial translation of 725 Å (ref. 14). The 725-Å axial spacing could also arise from anti-parallel packing of molecules 1400 Å long and the spot pattern observed in electron micrographs of native material, since it corresponds so closely to the lattice predicted by the X-ray pattern, may be due to the fact that neighbouring molecules are displaced by 290 Å relative to each other along the fibre axis (Fig. 2) and, in addition, the striations in the electron micrograph spaced 145 Å apart may indicate a sub-unit of this length in the molecule. The 29 Å pseudo-repeat would indicate a regular distribution within this sub-unit of amino-acids which bind silver atoms. It may be noted that paramyosin has a high helical content<sup>15</sup> (about 90 per cent) and the distance 145 Å corresponds to an integral number (98) of amino-acid residues along the fibre axis. The distance 29 Å does not correspond to an integral number of residues and this draws attention to the fact that the X-ray evidence requires only a pseudo-repeat and not a true repeat of this length. The actual distance along the fibre axis between any two silver atoms could lie between 28 and 31 Å and all such distances need not be the same.

It is possible, as suggested by Petruska and Hodge<sup>16</sup>, that the situation in paramyosin is similar to that in collagen where the tropocollagen molecule is thought to consist of sub-units of different length, and it is likely that the pseudo-repeat described here will help to fix some of the sub-unit parameters. A more precise description will await detailed analysis with the electron microscope and further investigation on the effects of metals on the X-ray pattern.

I thank Dr. R. D. B. Fraser and Mr. T. P. MacRae for their advice.

### Molecular Weight of Acid Proteinase of *Aspergillus saitoi*

THE recent development in this laboratory of methods for producing acid proteinase of *Aspergillus saitoi* (EC, 3.4.4.17, aspergillopeptidase A) from culture filtrate has made available sufficient material for a correlative study of its enzymatic properties<sup>1,2</sup>. The optimal pH for milk casein digestion is in the pH range of 2.5–3.0 and the proteinase is fairly stable over the pH range of 2.5–6.0 (ref. 3). Aspergillopeptidase A is capable of activating trypsinogen and chymotrypsinogen A at pH 4.5 (ref. 4). The further purification method for separating acid proteinase has been improved by chromatographic procedures with the use of ion exchange materials, 'Duolite OS-101', DEAE-cellulose and 'SE-Sephadex'<sup>5</sup>. The purified aspergillopeptidase A appears to be homogeneous on free boundary electrophoresis over a pH range of 2.0–10.0 and on ultracentrifugation at pH 4.1. The iso-electric point has been found to be at pH 3.65 in Sørensen's citrate buffer. In the investigation reported here, the molecular weight of aspergillopeptidase A was found to be 34,900 from sedimentation and viscosity, according to Scheraga–Mandelkern's formula<sup>6,7</sup>, and was also determined to be 34,200 according to Yphantis's treatment<sup>8</sup>.

For determination of the sedimentation constant<sup>9</sup> at zero concentration, runs were made at 59,780 r.p.m. with 0.438, 0.876, 1.313 and 1.751 per cent solution of aspergillopeptidase A in 0.1 M acetate buffer, pH 4.1, using a model 'E' Spinco analytical ultracentrifuge. All runs were made at room temperature. Five photographs were taken at 15-min intervals. The extrapolation has led to a value  $[S]_{0,w}$  of 3.33 S at zero concentration. The partial specific volume ( $\bar{V}$ ) of aspergillopeptidase A calculated from the specific volumes of constituent amino-acid residues<sup>10</sup> was calculated to be 0.722 ml./g. The specific volume values of the amino-acid residues are the values given by Meekin *et al.*<sup>11</sup>, and by Cohn and Edsall<sup>12</sup>. The buffer used for viscosity measurement contained 0.1 M acetate buffer, pH 4.1. Viscosity was checked at five different concentrations at 20° C. A value for intrinsic viscosity,  $[\eta]$ , of 0.032 dl./g was obtained.

The molecular weight was computed from the Scheraga–Mandelkern's formula<sup>7</sup>,

$$M = \frac{4690 [S]_{0,w}^2 [\eta]^{1/2}}{(1 - \bar{V} \rho)^{1/2}} \quad (1)$$

In equation 1 a value of  $\beta$  equal to  $2.16 \times 10^4$  has been used. With  $S = 3.33 \times 10^{-18}$ ,  $[\eta] = 0.032$  and  $\bar{V} = 0.722$ , the molecular weight is calculated to be 34,900.

The second method used for determination of the molecular weight of aspergillopeptidase A was Yphantis's procedure of sedimentation in the ultracentrifuge<sup>8</sup>. The molecular weight was calculated from:

$$M = \frac{1}{f c_s} \left( \frac{dc}{dr} \right)_{r=r_0} \frac{RT}{\omega^2 (1 - \bar{v} \rho)} \quad (2)$$

The molecular weight value of aspergillopeptidase A was checked at four concentrations using circular channel cells, and the individual values were obtained from the run at 12,500 r.p.m. in 0.1 M acetate buffer, pH 4.1, at 22° C. The time required to attain equilibrium was seen to be about 43 min. The extrapolation to zero concentration has led to  $M = 34,200$  with  $\bar{v} = 0.722$ , which is in fairly good agreement with the  $M$  value determined from sedimentation-viscosity measurement.

We thank Dr. K. Suzuki, National Institute of Radiological Science, for the operation of sedimentation analyses, and Dr. S. Yagisawa, University of Tokyo, for the measurement of molecular weight according to Yphantis's procedure.

## Quantitative Determination of Piperine with the Labat Reagent

In the presence of concentrated sulphuric acid and gallic acid, methylene-dioxyphenyl compounds produce a green colour which changes to blue when the solution is heated<sup>1</sup>. This reaction has been used to determine small amounts of methylenedioxyphenyl-containing pyrethrum synergists<sup>2</sup> and safrole<sup>3</sup>. Its application to the determination of the piperine content of pepper is described here.

Fig. 1. Absorption spectra of colours produced by formaldehyde and piperine and its degradation products after reaction with the Labat reagent. I, Piperine; II, Piperone acid; III, Piperonal; IV, Formaldehyde; V, Piperidine; VI, Reagent blank

The colour exhibits maximum absorption at 660 mμ (Fig. 1).

The reagent used consisted of 50 mg gallic acid (recrystallized 3 times from hot water) dissolved in 100 ml. of concentrated  $H_2SO_4$ . It was stored in an amber bottle under refrigeration and a fresh batch was made up every 2 weeks.

For colorimetric analysis, a standard curve was constructed as follows: 1 ml. containing 0.0–0.1 μM of piperine, m.p. 129°–130° C (K and K Laboratories, New York), dissolved in absolute ethanol, was placed in consecutive glass-stoppered borosilicate test-tubes. Nine ml. of the reagent was added, the tubes were loosely stoppered, heated in a boiling water bath for 60 min., and then cooled in an ice-water bath and allowed to stand at room temperature  $20^\circ \pm 1^\circ$  C for 30 min. The absorbance of the colour developed was then measured at 660 mμ against a reagent blank, similarly treated.

For the determination of the piperine content of pepper an alcoholic extract of the pepper (black or white) was prepared according to the method of Lee<sup>4</sup>. One ml. of an appropriate dilution was then used for assay.

Optimum conditions for reproducible assay are as follows: a heating time of 60 min at  $99^\circ \pm 1^\circ$  C, a level of 0.5 mg of gallic acid per ml. of the reagent and 36 N  $H_2SO_4$ . The reagent, stored in an amber bottle under refrigeration, is stable for 2 weeks and the colour developed is stable for at least 4 h. The method is highly reproducible and very sensitive when compared with other methods (Table 1). The standard deviation for 10 different determinations of piperine was found to be  $\pm 1.12$  per cent. Over three levels of 10, 20, and 30 μM of piperine added to pepper samples, average recoveries of 99.4–100.6 per cent were obtained. The molar extinction coefficient of the chromogen was found to be  $2.2985 \times 10^4$ . Beer's law held good over the range of 0.002–0.01 μM of added piperine per ml. of reagent. The standard curve may be described by the following equation:

$$x = 0.16415 y - 0.00118$$

where  $x$  = concentration of piperine per ml. of reagent,  $y$  = absorbance at 660 mμ.

Per cent piperine in sample =

$$\frac{x (0.028533) (\text{dilution factor})}{\text{Sample weight (milligrams)}} \times 100$$

Table 1. COMPARISON OF DETERMINATION OF PIPERINE CONTENT OF PEPPER SAMPLES BY DIFFERENT METHODS

Method used	Piperine content of peppers analysed*		
	A	B	C
	(white pepper)		
Ultra-violet spectrophotometric	6.70	5.70	5.00
Chromotropic acid	7.80	7.40	6.85
Labat's reaction	7.76	7.45	6.25

\*Average of five determinations

The mechanism involves the cleavage of the methylenedioxy group in the presence of strong sulphuric acid to produce formaldehyde which couples with gallic acid to form a coloured product. Therefore, piperic acid, piperetine and chavicine<sup>5,6</sup> will respond. As a result, the method measures "the total bite principles of pepper", as does the chromotropic acid method.

All compounds which contain the methylenedioxy group or which can produce formaldehyde in the presence of concentrated  $H_2SO_4$  as well as the ethylenedioxy group<sup>7</sup> glycolic, tartaric, glyceric and glyoxylic acids will also respond to the Labat test<sup>8</sup>. However, under the conditions of extraction of the piperine with ethanol<sup>4</sup> it is highly unlikely that interference from these sources will be encountered, since such substances are either present in pepper at rather low levels or will not be readily extracted. Other possible precursors of formaldehyde listed by Berova<sup>7</sup> can likewise be ignored. The possible contribution of glucose due to the  $-CH_2OH$  grouping as shown by

Beroza is much lower in this procedure than in the chromotropic acid method<sup>1</sup>. This is due largely to the fact that with chromotropic acid the wave-length of maximum absorption of the glucose colour is the same as for piperine (580 mμ), whereas with the Labat reagent the glucose colour has maximum absorption at 540 mμ, which is appreciably removed from the absorption maximum (660 mμ) for the piperine colour.

This method, in conjunction with the development of colorimetric methods based on colour complexes formed by piperine with alkaloid reagents, and coloured salts formed with some of the concentrated acids<sup>2,3</sup>, can provide useful and easily executed alternatives to the methods now being used for the determination of the piperine content of pepper. The reagent as described is more stable than the chromotropic acid reagent which is usually prepared daily.

## Use of Methylene Blue for Staining Sialomucoproteins on Paper

FOR some time we have used in our laboratory a simple and sensitive method for the location of sialomucoproteins separated by electrophoresis on paper.

Whatman No. 3 MM paper strip (10 cm wide × 34 cm long) was moistened with a volatile buffer solution such as pyridine-acetic acid-water (10:0.4:90, by volume) buffer of pH 6.5 (ref. 1) and then pressed between two sheets of filter paper to remove the excess of the buffer. The strip was then placed in an electrophoretic apparatus. Sample solution containing sialomucoprotein was applied at the origin. Electrophoresis was carried out in the buffer by the horizontal open strip method at 200 V for 7 h and platinum electrodes were used. After electrophoresis the strip was allowed to dry overnight at room temperature. The dry strip was immersed in a solution of methylene blue (100 mg of Merck's methylene blue 'B' was dissolved in 200 ml. of 90 per cent methanol) for 20 min, and excess dye was removed by washing with 90 per cent methanol until the strip had only a light blue tint. The strip was then dried at room temperature. The sialomucoprotein gave a blue, while acid mucopolysaccharides such as chondroitin, chondroitin sulphate, hyaluronic acid and heparin gave each a blue violet, metachromatic spot under the same conditions.

Methylene blue gave better results than toluidine blue and alcian blue for the staining of sialomucoproteins under the same conditions.

We thank Prof. T. Furuhashi for his advice.

## Portal Venous Transport of Free Pelargonic Acid following Intestinal Instillation of Tripelargonin

SATURATED odd-chain fatty acids such as valerate (C5) and pelargonate (C9) are metabolized differently from even-numbered saturated fatty acids in the same range of carbon-chain length, caproate (C6) and caprylate (C8)<sup>1-4</sup>. The three terminal carbons of the odd-chain acids appear to be metabolized as a unit, which can serve as a carbohydrate precursor, in contrast to the behaviour of the terminal two-carbon units of even-chain acids. Digestion of glycerides of odd-chain fatty acids and absorption and transport of the digestion products appear to have been little studied.

This communication describes experiments with tripelargonin suggesting that, in the dog, this triglyceride is hydrolysed in the gut with the resulting C9 acids transported in the portal vein in the free fatty acid (FFA) form.

Dogs were lightly anaesthetized with sodium pentobarbital and a polyethylene catheter was implanted in the portal vein. Thirty-five g tripelargonin homogenized with 20 ml. of a 2.5 per cent aqueous solution of sodium taurocholate was injected directly into the duodenal lumen. The pylorus was occluded by a non-traumatic clamp during the 5-min instillation period. After the injection the portal vein catheter was exteriorized and the abdomen closed. The catheter was kept open by means of a slow infusion of 0.9 per cent saline solution. Samples of blood were obtained from the portal vein before, and at frequent intervals for 4 h after, intraduodenal instillation of the glyceride. The lipids were extracted from each plasma sample and the lipid residue separated by thin-layer silicic acid chromatography into phospholipid, free cholesterol, FFA, triglyceride and cholesterol ester. The lipid esters and FFA were eluted with chloroform-methanol and the fatty acid moieties were identified by gas-liquid chromatography (GLC) following methylation. To provide a sufficient quantity of lipid ester for fatty acid analysis, the post-prandial samples were pooled by lipid ester class. Samples were run at both high (175°C) and low (100°C) column temperatures in order to obtain a more complete spectrum of fatty acids.

Results in one experiment are shown in Figs. 1 and 2. In Fig. 1 are shown the fatty acid patterns by GLC of the FFA from portal venous plasma in the post-absorptive state and 2 h after intraduodenal instillation of tripelargonin. Under both high and low column temperatures, post-absorptive portal plasma FFA did not contain any fatty acid below C<sub>14</sub>. However, in the post-prandial sample, pelargonic acid was readily demonstrated in the FFA fraction. In contrast, the lipid ester fractions from the post-prandial plasma did not contain any detectable amount of pelargonic acid under either high or low temperature column conditions (Fig. 2).

Fig. 1. Gas-liquid chromatograms of free fatty acids in canine portal venous plasma before (A) and 2 h after intraduodenal instillation of tripelargonin (B). Pelargonic acid is readily identified (arrow) in the post-prandial plasma at both high (left) and low (right) column temperatures.

Fig. 2. Gas-liquid chromatograms of the fatty acid moieties of three lipid ester fractions in canine portal venous plasma during a four-hour period following intraduodenal injection of tripelargonin: A, Triglyceride; B, Cholesterol ester; C, Phospholipid. Pelargonio acid cannot be identified at either high (left) or low (right) column temperatures.

Since only non-esterified pelargonio acid appeared in the portal venous plasma following the intraduodenal administration of tripelargonin, it must be inferred that the triglyceride was first hydrolyzed in the intestine. Indeed, the mechanism of absorption and portal venous transport of pelargonate appears to be similar to that reported for caprylate<sup>4,5</sup>. It seems unlikely that any significant portion of the pelargonate travelled by the lacteal-thoracic duct system since our own (unpublished) experiments in rats have shown that pelargonio acid comprised less than 5 per cent of the total fatty acids recovered from thoracic duct lymph during a 24-h collection period after oral administration of tripelargonin.

It is concluded that after intestinal hydrolysis of the parent triglyceride, the absorbed pelargonate is transported principally in the portal vein as a free acid.

### Heterogeneity of the Protein Moiety of the Human Serum High-density Lipoproteins

THE possibility of preparing a water-soluble, essentially lipid-free protein,  $\alpha P$  (ref. 1), from human serum high-density lipoproteins (HDL) of  $d$  1.063–1.21 gm/ml. has provided a means for studying its physical and chemical properties and the reason for its high avidity for lipids<sup>2</sup>. As a partial aid to the elucidation of these problems a comparative analysis of the antigenic properties of HDL and  $\alpha P$  was conducted. Normal human serum HDL was separated by flotation at density between 1.063 and 1.21 gm/ml. (NaCl–NaBr) in a Spinco model L ultra-

centrifuge (40.3 rotor, 114,480g, 18° C, 24 h) and re-spun for an additional 48 h under the same conditions to remove serum protein contaminants.

$\alpha P$  was prepared from HDL by a modification of the procedure of Soanu *et al.*<sup>1</sup> and dissolved in buffer (tris hydroxymethylamino methane), pH 8.6, 0.1 ionic strength. For immunization, rabbits were injected intramuscularly with HDL or  $\alpha P$  suspended in complete Freund's adjuvant, at weekly intervals for a total of 4 weeks. Blood was taken 8 days after the last injection. Antibody titres were determined according to Kabat and Meyer<sup>3</sup>. Immunodiffusion studies in agar gel (Bacto Agar, Difco Laboratories, Detroit) were conducted according to Ouchterlony<sup>4</sup> and Scheidegger<sup>5</sup>. By agar electrophoresis (Fig. 1A) HDL showed a major fast band stainable for protein (Amido Schwartz) and lipid (oil red O) and a minor slow one detected only by protein stain. With  $\alpha P$ , the major band was close to the origin, while a faint one moved anodically in the  $\alpha_1$ -globulin area. Immuno-electrophoretic analysis of HDL using anti-HDL or anti- $\alpha P$  sera showed three protein stained arcs of precipitation: only the major one (Figs. 1B and C) was detected by lipid stain. Three arcs of precipitation, lipid-fast, were noted in reactions between  $\alpha P$  and anti- $\alpha P$  or anti-HDL sera (Figs. 1B and C). The position of the major arc, as compared with HDL, was closer to the origin, an expression of the low mobility of  $\alpha P$  in agar gel<sup>6</sup>. Antigenic heterogeneity of either HDL or  $\alpha P$  was also detected by the Ouchterlony technique (Fig. 1). Anti-HDL sera adsorbed with  $\alpha P$  failed to react with HDL. Similarly, no reaction was noted between  $\alpha P$  and anti- $\alpha P$  sera, after adsorption with HDL. Immuno-electrophoretic analysis of mixtures of HDL and  $\alpha P$  (HDL:  $\alpha P$ ; 2.0:1; 1:1 and 0.5:1) against anti-HDL sera gave results similar to those seen with whole HDL. However, the intensity of the arc of precipitation closest to the origin varied according to the concentration of  $\alpha P$  in the mixture. Both HDL and  $\alpha P$  exhibited a high electrophoretic mobility in a neutral gel medium ('Agarose, J-2404-S', Fisher Scientific Co., Chicago). The immunodiffusion patterns were the same as those in plain agar.

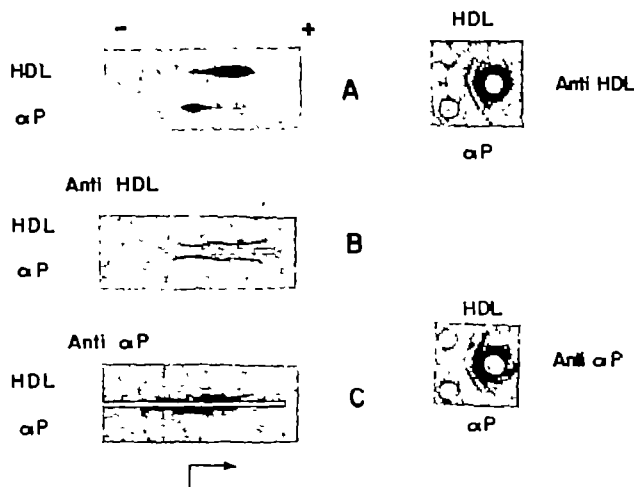

Fig. 1. Electrophoresis and immunodiffusion patterns in agar gel of HDL or  $\alpha P$  against anti-HDL or anti- $\alpha P$  sera. Conditions of electrophoresis: 'LKB Immaphor' apparatus (Stockholm, Sweden), veronal buffer, pH 8.6, ionic strength 0.04, 6 V/cm, 40 m. amp, 2 h, 25° C. Protein stain: amido Schwartz.

From these investigations it would appear that HDL, separated by ultracentrifugation, exists as a mixture of lipid-rich ( $\alpha LP$ ) and lipid poor ( $\alpha P$ ) forms, readily dissociable by agar electrophoresis. This conclusion, which is in agreement with that derived from preliminary findings by Levy and Fredrickson<sup>7</sup>, may not apply to circulating HDL.

The fact that HDL and  $\alpha P$  produced in rabbits an identical qualitative immunological response seems to favour the concept that the antigenicity of HDL resides in its protein moiety. However, quantitative immunoprecipitation experiments in the presence of either HDL or  $\alpha P$  showed a significantly higher activity of anti-HDL sera as compared with anti- $\alpha P$ , thus suggesting that HDL lipid, which is inert by itself<sup>8</sup>, has an enhancing effect on the antigenic activity of the protein moiety,  $\alpha P$ .

Antigenic homogeneity of  $\alpha P$  was previously noted by Scann *et al.*<sup>6</sup> during investigations using horse anti-normal human sera. Discrepancy between previous and present findings was related to the difference in antibody potency, weaker antisera being able to detect only the major of the three antigenic determinants. The reasons for the antigenic heterogeneity of HDL, recently reported also by Ayrault-Jarrier *et al.*<sup>9</sup> and Burstein and Fine<sup>10</sup>, are not clear. The position of the area of precipitation in the agar plates suggests that the three antigenic determinants of  $\alpha P$  are different in size and/or charge. That  $\alpha P$  may exist in solution as molecular forms containing a various number of monomeric units is indicated by the work of Shore<sup>11</sup>. It is possible, however, that  $\alpha P$  heterogeneity is related to changes of the primary amino-acid sequence of its polypeptide chains or of their carbohydrate content<sup>12</sup>. Work in progress on  $\alpha P$  fragments obtained by chemical or enzymatic cleavage of HDL protein may shed light on this problem.

### Effect of Freezing and Thawing on the Stability of Double Helix of DNA

INCREASING attention has been directed in recent years to the effects of freezing and thawing on the structural and functional integrity of various biological materials, especially from the point of view of low-temperature storage. At the level of isolated enzyme proteins, it has been shown that there exists a critical region of temperature in which some proteins are denatured during freezing and thawing. The range in which the maximal level of denaturation was produced is, for example, from  $-12^{\circ}\text{C}$  to  $-75^{\circ}\text{C}$  for catalase, and from  $-20^{\circ}\text{C}$  to  $-72^{\circ}\text{C}$  for myosin<sup>1,2</sup>.

On the other hand, there is little information concerning the effects of freezing and thawing on the stability of deoxyribonucleic acid, that is, the genetic material.

This communication deals with the effects of freezing and thawing on the stability of double-stranded helical

structure of calf-thymus DNA in terms of the hyperchromic effects at 259 m $\mu$  on denaturation. Calf-thymus deoxyribonucleic acid used was a preparation from Sigma Chemical Co. (sodium salt, type 1). This preparation was characterized by its extinction per gram-atom of phosphorus at 259 m $\mu$ , the value of which  $\epsilon(p)$  was 6650. The 'melting' temperature ( $T_m$ ) for this preparation was also determined as follows: 3.5 ml. samples of DNA solution (30  $\mu\text{g}/\text{ml}$ .) were heated in stoppered tubes in a thermostat set to each required temperature. After 10 min the heated samples were removed and cooled rapidly to  $0^{\circ}\text{C}$  in a few seconds, and the spectroscopic measurements were carried out at room temperature. In 0.15 M sodium chloride plus 0.5 mM phosphate buffer (pH 7.0), the 'melting' temperature was  $91.5^{\circ}\text{C}$  and it was decreased to  $59.0^{\circ}\text{C}$  in 0.5 mM phosphate buffer, pH 7.0. These results for  $T_m$  were almost similar to those reported by Lee *et al.*<sup>3</sup>.

In my experiments, the effects of freezing and thawing on the ultra-violet absorption of DNA were investigated under the following conditions: 3.5 ml. samples of DNA solution (30  $\mu\text{g}/\text{ml}$ .,  $5.5 \times 10^{-4}$  M in phosphorus) were placed in test-tubes and frozen by immersion in a low-temperature bath for a given time. The frozen samples were then removed and thawed rapidly in a bath at  $20^{\circ}\text{C}$ , and the spectroscopic measurements were carried out at room temperature ( $20^{\circ}\text{C}$ ). All control samples were immersed without freezing in an ice bath at  $0^{\circ}\text{C}$ .

Table 1 shows the percentage increase in the absorbance at 259 m $\mu$  on freezing DNA for 10 min at each temperature. In 0.15 M sodium chloride plus 0.5 mM phosphate buffer, pH 7.0 ( $T_m = 91.5^{\circ}\text{C}$ ), no increase in the ultra-violet absorbance of DNA by freezing and thawing was observed. In 0.5 mM phosphate buffer ( $T_m = 59.0^{\circ}\text{C}$ ), on the other hand, there occurred a slight decrease, rather than some increase, in the absorbance at 259 m $\mu$  by freezing and thawing. These circumstances were the same with the time of freezing for 5 min to the next few hours, and also the same with the concentrations of DNA of 3  $\mu\text{g}/\text{ml}$ –30  $\mu\text{g}/\text{ml}$ . The slight decrease (less than 5 per cent) in the ultra-violet absorbance which occurred by freezing DNA in the low ionic strength may be attributed to the possibility that some partial loosening in the helical structure of the DNA used has become tighter by freezing.

In the range of temperature that has been investigated, down to  $-192^{\circ}\text{C}$ , it can be concluded, therefore, that the double-stranded helical structure of DNA would not be broken down by freezing and thawing, in terms of the hyperchromic effect of denaturation.

As compared with the fact that there exists a definite critical region of temperature for denaturation of proteins by freezing and thawing, the remarkable stability of the

## PHYSIOLOGY

### Heart Valve Lesions following Papillary Muscle Damage

THE genesis of rheumatic valvular disease in man has been difficult to establish owing to the scarcity of human material in the early stages and the absence of any comparable condition in experimental animals. On the evidence at present available it has been stated that the calcific lesions found in human rheumatic valvular disease are unlikely to be the direct result of the rheumatic process in the valve cusps<sup>1</sup>. In recent experiments we have been studying the effects of papillary muscle damage and inactivation on the function of the mitral valve and the left ventricle of the dog<sup>2</sup>. In these experiments either the anterior or the posterior papillary muscle was injected with 0.5–1.0 ml. ethanol and the animal allowed to recover. A surprising finding was that when the animals were killed three months later, four out of twelve dogs in addition to papillary muscle damage also had fibrotic, calcific or chondritic lesions of the mitral valve cusps (Fig. 1). In all four animals the valvular lesion was in the segment of the aortic cusp of the mitral valve which was attached to the damaged papillary muscle and there was no continuity of the valvular lesions with either the papillary muscle lesion through the chordae tendinae or the atriotomy scar in the three animals in which this had been carried out. In ten dogs used as controls in which the ethanol injection was made into the lateral wall of the left ventricle between the papillary muscles, no valvular lesions were found. Histological examination of the lesions showed a fibrous plaque on the atrial surface of the valve cusp with replacement by calcification and chondrification (Fig. 2). There was no evidence of an infective lesion.

Chondrification of endothelial vascular tissue in response to trauma has been reported previously in both dogs and

Fig. 1. Open left ventricle of dog, 10 weeks after injection of papillary muscle. Area of papillary muscle damage and lesion on aortic cusp of mitral valve outlined.

chickens<sup>3-5</sup>. Cartilaginous tissue was found in the chicken beyond an artificial coarctation<sup>4</sup> and it was suggested that it was the consequence of abnormal compression forces; but invagination of the left atrial appendage over a silastic ball, although producing papilliform excrescences on the heart valves, did not produce chondrification within the heart<sup>5</sup>.

Endoscopic photography in these animals has shown excessive 'flutter' in the valve cusps and mitral incompetence<sup>7</sup>. Our present results suggest that the absence of normal papillary muscle action may give rise to abnormal stresses within the valve cusps which may produce calcific and chondritic lesions. It is therefore possible that in human valvular disease, also, calcification is the consequence of traumatic stress.

This research was carried out under a grant from the Scottish Hospitals Endowment Research Trust.

### Some Behavioural Correlates of the Transcephalic d.c. Potential in Cats

NEURAL direct current (d.c.) potentials have recently received much attention<sup>1</sup>. A steady d.c. potential across amphibian cortex in a fronto-occipital plane has been observed<sup>2</sup>. These measurable exterior surface potentials are correlated with anaesthesia and sleep<sup>3,4</sup>. High correlations have been reported between transcephalic d.c. potential (measured between mid-forehead to low union), level of anaesthesia and electro-encephalograph (EEG)<sup>1</sup>. In the awake state the surface-recorded steady potentials are frontally negative, while in anaesthesia the frontal

negativity decreases, that is, the forehead becomes more positive with respect to the occiput. The general relationship between EEG activity and behaviour (sleep-wakefulness) of humans and animals is, of course, well known<sup>6,7</sup>. This correlation of behaviour and EEG breaks down following the administration of anticholinergics such as atropine<sup>8</sup>. The EEG activity is slowed, whereas the animal appears excited. Such dissociation of EEG and behaviour under atropine has been observed in cat<sup>8</sup>, dog<sup>10</sup> and rabbit<sup>11</sup>.

Becker *et al.*<sup>12</sup> have suggested that the organized d.c. activity of the brain functions as a controlling mechanism by influencing the rate of message-flow action potentials, that is, that this potential represents a primitive form of control system. They raise the possibility that this d.c. potential state was the original functioning system in the first primitive nerve nets. It seems reasonable to assume that if the organized d.c. activity of the brain represents a sort of primitive control system, such steady potentials should be a more stable (less easily modified) reflexion of observed behaviour under certain basic physiological conditions than the EEG. This examination attempted to investigate the preceding assumption by recording EEG and d.c. fronto-occipital potentials from atropine-treated cats. Four adult male cats with food and water available *ad lib.* were used.

A Hewlett Packard d.c. meter in conjunction with large surface carbon saline electrodes<sup>13</sup> was used to determine bioelectric d.c. potentials and a Grass model 5 polygraph to record EEG. A commercial shielded observation box was used to contain the animal.

Five stainless-steel wire electrodes were placed on the calvarium of each of four adult male cats anaesthetized with pentobarbital under aseptic conditions. Each wire was soldered to a contact on a miniature socket which was anchored to the calvarium of each cat with dental cement. Five weeks of convalescence were allowed before the first individual testing. Each cat was extensively pre-handled and given five successive days of 0.5 h unrestrained exploration (adaptation sessions) in the observation box. On the initial test day parietal-occipital EEG was recorded for several minutes, and the fronto-occipital d.c. potential (mV) measured. Each cat was then immediately injected intraperitoneally with either 2 mg/kg atropine in 5.0 c.c. 0.9 per cent saline or 5.0 c.c. saline alone. Half the cats received atropine with saline and the other half only saline. Following a 30-min observation period of gross behaviour, EEG and d.c. potential were again recorded. Five to seven days later the foregoing procedure was repeated, but those animals that had received atropine with saline were given saline alone and vice versa. Approximately two weeks later each cat was placed in the observation box, the d.c. fronto-occipital potential measured and 2 mg/kg atropine injected intraperitoneally. Measurements of d.c. potential were taken 30 sec after the injection and again after a 30-min interval.

Prior to atropine or saline injection, parietal-occipital EEG recordings associated with semi-alertness were obtained from each of the four cats tested. Thirty min after atropine injection (2 mg/kg) the EEG recordings were of typical sleep pattern. The usual manifestations of atropine were observed following injection, that is, pupil dilation, tachycardia, etc. Thus, under atropine the classical behavioural dissociation occurred. No changes were found in observed behaviour or EEG activity after saline administration compared to the pre-injection measurement. No appreciable differences occurred in the d.c. potentials of cats receiving saline alone as compared with those receiving atropine, that is, no d.c. potential shift occurred. The d.c. potential reflected observable behaviour, the EEG did not. These data are summarized in Table 1.

When d.c. potentials were measured immediately before atropine injection, 30 sec after injection and again at

Table 1. EEG, BEHAVIOUR AND FRONTO-OCCIPITAL D.C. CHANGES UNDER ATROPINE AND SALINE INJECTION

Cat	Pre-injection			30 min post-injection		
	EEG pattern	Behaviour pattern	d.c. Potential (mV)	EEG	Behaviour	d.c. Potential (mV)

4	Awake	Alert	+8	Awake	Alert	+4

30 min, a positive d.c. shift occurred at the 30-sec measurement. The forehead of each cat, compared with the pre-injection measurement, became more positive with respect to the occiput 30 sec after injection. The relative positivity was transient and 30 min later the standing d.c. potential no longer showed any consistent pattern compared with the pre-injection level for each animal. These data are given in Table 2.

Table 2. EFFECT OF ATROPINE ON THE FRONTO-OCCIPITAL D.C. POTENTIAL (mV)

Cat	Pre-injection	30 sec Post-injection	30 min Post-injection
1	+0.5	0.0	0.0

3	-4.0	+1.0	+2.0
4	+1.0	+8.0	+2.0

Previous investigations have indicated high correlation between sleep-wakefulness cycles, EEG and transecephalic d.c. potentials. This work has demonstrated a dissociability of EEG and fronto-occipital d.c. potentials with this standing potential retaining a much closer relationship with observable behaviour. The d.c. potential was not correlated with atropine administration. Atropine produced EEG sleep patterns but did not produce a uniform positive shift of the d.c. potential. Therefore, the d.c. potential was a more accurate representation of observable behaviour. It may be speculated, then, that the transecephalic d.c. potential underlies EEG activity and represents the more fundamental parameter of nervous activity.

The transient positive d.c. shift obtained immediately (30 sec) after injection may suggest the momentary internal stimuli orientation of a primitive control system. To evaluate this internal stimuli orientation a preliminary food deprivation investigation was carried out. Water was available *ad lib.* during this food deprivation period. Fronto-occipital d.c. potential measurements (mV) were taken on ten individually caged adult male cats deprived of food for 24 h. Following these initial d.c. measurements, the cats were fed commercial cat food, and 30 min after eating the standing d.c. potential for each animal was again determined. In nine of the ten cases: (a) the forehead was negative with respect to occiput prior to food intake; (b) 30 min after eating the fronto-occipital potential had become more positive. As evaluated by the Mann-Whitney *U* test, these positive d.c. potential shifts are statistically significant ( $P < 0.05$ ). These data again tend to support the suggestion of Becker *et al.* that the organized d.c. activity of the brain represents some primitive form of control system inasmuch as nutrient intake may logically be considered an essential function. Speculatively, the relative frontal negativity noted before eating may represent a generalized activation of the organism toward external stimuli, while the positive d.c. shift after food intake may be ascribed to a different orientation, that is, toward internal stimuli. The measurements obtained 30 min after atropine injection offer little information on the external-internal stimuli hypothesis as atropine modified both exteroceptive input (pupil dilation) and interoceptive input (tachycardia).

The data obtained following atropine administration tend to support the suggestion of Becker *et al.*<sup>12</sup> that the organized d.c. activity of the brain represents a primitive

form of control system inasmuch as such steady potentials were dissociable from EEG under atropine and yet paralleled observable behaviour. If the d.c. potential shift immediately following enteric stimulation represents a primitive parameter of system arousal then it may be of interest to investigate EEG manifestations associated with various d.c. potential patterns.

### Underwater Breathing Device utilizing Oxygen dissolved in Water

THE respiration of an animal can be supported if its expired air is re-oxygenated, freed of carbon dioxide, and re-inhaled. At the water's surface dissolved gases equilibrate with the air above, providing a partial pressure of oxygen ( $pO_2$ ) of approximately 150 mm Hg. The thickness of the water layer with an oxygen concentration approximating that at the surface varies widely in the oceans; in the Atlantic south of 50° S. it extends to about 50 m depth, and at 100 m the water is still 90–95 per cent saturated<sup>1</sup>. In expired air of man  $pO_2$  is 116 mm Hg (ref. 2). Thus, for a considerable distance from the surface there exists a  $pO_2$  gradient of roughly 35 mm Hg from water to expired air. Since the partial pressure of carbon dioxide ( $pCO_2$ ) in water is negligible, a gradient exists for the diffusion of  $CO_2$  from expired air to water.

An apparatus was constructed to allow a guinea-pig to maintain respiratory exchange by means of these diffusion gradients (Fig. 1). A 'Teflon' membrane was interposed

between the guinea-pig's expired air and the water; the air above the water was at atmospheric pressure. Oxygen diffused into the expired air and carbon dioxide diffused out. The gas mixture was then re-breathed by the guinea-pig.

Fifteen membrane units were supported on an open frame and had a combined surface area of 5.9 m<sup>2</sup>. Each unit was made by placing screening between two 'Teflon' membranes 12.5  $\mu$  thick. Expired air flowed between the two membranes, which were sealed by autoclavable masking tape. A manifold at each end of the apparatus led to one side of a respiratory valve attached to the trachea of an anaesthetized guinea-pig. All membranes were submerged but the apparatus was kept close to the surface by two buoyant pieces of plastic. The animal was secured to the apparatus above the water. The membrane array moved through the water at approximately 6 m/min. Gases entered at the back and left at the front relative to movement through the water, the purpose being to aid diffusion by countercurrent. It was realized that the effect might be small in this case.

The pool was 3.5 m by 1.9 m. It was filled to a depth of 0.7 m with tap-water aerated for 12–16 h. The aeration was stopped and the water was allowed to stand from 2 to 24 h. The  $pO_2$  of the water at the time of experimentation was within 4 mm Hg of that of the room air. The  $pO_2$  and  $pCO_2$  of water and gases were measured with modified Clark and Severinghaus electrodes using a 'Model 105' Instrumentation Laboratory meter.

In each of two experiments a guinea-pig was anaesthetized, a tracheotomy performed, and a tracheal cannula connected to a respiratory valve. The valve allowed exhaled gas to enter one end of the membrane array and the animal to re-breathe gas from the other end. Respiratory frequency,  $pO_2$  and  $pCO_2$  of expired and inspired gases were measured. Nitrogen equal in volume to the withdrawn gas samples was added to the closed circuit.

The possibility existed that room air would leak into the system through the tracheotomy or valve. Consequently, at the conclusion of each experiment the animal and valve were disconnected from the membrane array and connected to a 'control apparatus', consisting of a closed circuit of Erlenmeyer flasks with volume totalling that of the membrane array. If there were no air leaks one would expect that within the control apparatus oxygen would quickly be used up and carbon dioxide would accumulate.

An animal weighing 306 g was used in the first experiment. There was a rise in  $pO_2$  as expired air passed through the apparatus. The rise is seen as the difference between the expired  $pO_2$  and inspired  $pO_2$  (Fig. 2) and resulted primarily from oxygen diffusion from the water but to a lesser extent from oxygen trapped within the apparatus at the beginning of the experiment. For the first 3.5 h the  $pO_2$  of the inspired and expired gases fell, thereby causing an increase in the diffusion gradient for oxygen from water to expired air. As a result, the quantity of oxygen that diffused across the membrane increased until it equalled the amount of oxygen utilized by the animal. This occurred after 3.5 h; at that time the  $pO_2$  of inspired and expired gas were constant and remained so for an hour. The respiratory frequency rose, however, presumably because of increasing hypoxia and fatigue. Shortly after disconnecting the animal from the apparatus its respiratory rate was 32 and the minute volume was 100 ml. From the respiratory parameters it was calculated that the apparatus furnished approximately 4.0 ml. oxygen/min or transferred 0.68 ml. oxygen/m<sup>2</sup>/min.

At the end of the experiment the animal was attached to the control apparatus. Within the first 15 min  $pO_2$  went from 146 to 52 mm Hg and  $pCO_2$  from nearly zero to 107 mm Hg. We conclude that there was no significant air leakage through the valves or tracheotomy.

In the second experiment (Fig. 3) a guinea-pig weighing 211 g was used, but the membrane apparatus was first

Fig. 1. Underwater breathing apparatus consisting of 15 'Teflon' membrane units. The exhaled air of a guinea-pig enters the membrane units; oxygen diffuses in and carbon dioxide diffuses out. The air is then re-breathed. Cross-section of a membrane unit is shown.

flushed with an air-nitrogen mixture of  $pO_2$  108 mm Hg. The inspiratory  $pO_2$  this time rose for the first half-hour and thereafter the inspiratory  $pO_2$ , expiratory  $pO_2$ , and expiratory  $pCO_2$  showed little change. After 5 h the animal was connected to the control apparatus containing gas of initial  $pO_2$  of 128 mm Hg and a  $pCO_2$  close to zero. After 10 min  $pO_2$  was 85 mm Hg,  $pCO_2$  55 mm Hg, and the animal's respiratory rate was 50.

In both experiments the  $pCO_2$  of the inspired gas remained below 10 mm Hg. A control experiment showed that in a membrane unit with comparable gas flow per unit area (no animal attached) the  $pCO_2$  fell from an initial 23 mm Hg to 2 mm Hg. Also, decreasing the gas flow into the apparatus led to a higher  $pO_2$  of gas leaving since more time was allowed for equilibration. It was not, therefore, surprising that the smaller animal had the higher inspiratory  $pO_2$ , one which remained within physiological range.

The membrane apparatus allowed transmembrane diffusion of oxygen and carbon dioxide at the rates at which the animal utilised oxygen and gave off carbon dioxide. We conclude that respiratory gas exchange can be maintained with the apparatus for an indefinite period of time.

The apparatus described has, however, certain inherent limitations. Sea-water contains at best only 9 ml. of oxygen per litre<sup>1</sup>. Thus, a large quantity of water as well as a large membrane surface area are necessary to support the respiration of even a small animal. More significantly, the apparatus described can function only within a metre of the water's surface. As a diver goes deeper the air pressure within his chest must equal the increasing water pressure. Nitrogen furnishes four-fifths of air pressure. As total intrathoracic pressure is increased the partial pressure of nitrogen within the system is also increased. Nitrogen would then diffuse from expired air to water; therefore nitrogen cannot be used to maintain a high pressure within the system. However, if a physiologically inert gas could be found to which a given membrane were impermeable, a small amount of the inert gas would last indefinitely to maintain a pressure equal to hydrostatic pressure. The membrane, if it were permeable to oxygen and carbon dioxide while impermeable to the inert gas,

Fig. 3. Respiratory parameters as a function of time after attaching a 211-g animal to the membrane apparatus which was first flushed with an air-nitrogen mixture

would then allow oxygen flow regardless of hydrostatic pressure.

We thank Dr. John F. Perkins, jun., for his many helpful suggestions.

## Hypophysectomy and Blood Sugar Regulation in a Cyclostome, *Myxine glutinosa*

THE removal of the pituitary has contributed to the understanding of the endocrinology of many groups of vertebrates. However, ablation of what is probably the most primitive extant pituitary<sup>1,2</sup>, namely that of a myxinoide cyclostome, has, to the best of our knowledge, not yet been reported.

This operation has been successfully performed recently on the hagfish, *Myxine glutinosa*, at Kristineberg Zoological Station, Sweden. The animals were anaesthetized by immersion in 0.25 per cent propylene phenoxetol (Nipa Laboratories Ltd.) for 10–15 min<sup>3</sup>. A ventral approach was used, a median incision being made in the skin just behind the mouth for a distance of about half an inch. The protractor muscles, that is, the copulo-glossus profundus and superficialis muscles and the copulo-palatinus muscles, were retracted back from the centre line. The retraction exposed the basal plate which was medially bisected with a sharp scalpel. The fore-gut in the region of the lingual teeth thus exposed was retracted to one side to reveal the caudal termination of the cartilaginous floor of the nasohypophyseal canal. This cartilage was then bisected back from the junction of the nasohypophyseal canal with the fore-gut to expose the pituitary lying embedded in the cartilage forming the roof of the nasohypophyseal canal

Fig. 2. Respiratory parameters as a function of time after attaching a 306-g animal to the membrane apparatus

and floor of the brain. Using oblique light the oval patch marking the position of the adenohypophysis could be seen. With the aid of a fine scalpel and a binocular dissecting microscope a rectangle of cartilage containing the pituitary was removed, exposing the hypothalamus. The cavity was plugged with sterile gelatine sponge. The wound was ligatured in the usual manner. On return to water the hypophysectomized animals resumed active respiratory movements within 10–20 min and were kept in aquaria for periods up to three weeks. As control experiments, isolated mechanical lesions were made in the hypothalamic region. Sham operations included exposure of the pituitary without its removal. Microscopic examinations were carried out at autopsy to ascertain the completeness of pituitary removal and the extent of the hypothalamic lesions. Repeated blood samplings were performed *in vivo* via the large caudal venous sinuses and the blood glucose-level was assayed by the glucose oxidase method as described previously<sup>4</sup>. Altogether 23 hagfish were successfully hypophysectomized and 7 were used as controls.

The most surprising feature of the operation was that, unlike the lamprey<sup>5,6</sup>, the hagfish did not become strikingly pale after the operation; no change in pigmentation could be observed. This might be taken to imply the absence of melanocyte-stimulating hormone, although Adam<sup>7</sup> has quoted unpublished data reporting that extracts made from the ventral hypothalamus and adenohypophysis of hagfish produce skin colour changes in *Bufo viridis*.

Both hypophysectomy and hypothalamic lesions, and to some extent also the sham operations, caused an increase in blood glucose values, from about 16 mg/100 ml. to about 60 mg/100 ml., one or two days after the operations. After 10–20 days these elevated values returned to normal. No continued hyperglycaemia was observed in spite of force-feeding the hagfish. Thus, it must be concluded that the elevated blood sugar was a stress response and not due to the presence in the pituitary gland of a factor influencing blood sugar values.

Having provided a technique for hypophysectomy of *Myxine* it is hoped that the equivocal situation of pituitary regulation of adrenal cortex, thyroid, and gonads in myxinoidea might be investigated.

## PHARMACOLOGY

### A Highly Selective Carcinolytic Agent Isolated from Cobra Venom

CRUDE cobra venom contains a number of proteins which can be demonstrated by agar electrophoresis (pH 8.3) (Fig. 1a). By the use of column chromatography in carboxymethyl cellulose and ammonium sulphate fractionation of cobra venom, it has been possible to

Fig. 1. Agar electrophoresis of cobra venom. a, Whole venom; b, the neurotoxin; c, the fraction of low toxicity which produces lysis of tumour cells.

separate the protein fraction which is responsible for the toxicity of the venom in whole animals (Fig. 1b) from another fraction which has low toxicity and remains close to the origin in agar electrophoresis, using the method of Wieme and Rabeys<sup>1</sup>. This is shown in Fig. 1c. The *MLD* for this fraction was 100, whereas the *MLD* for the crude venom and the neurotoxin was 17 and 4, respectively (the *MLD* minimum lethal dose in  $\mu$ g of protein of the material required to kill a mouse weighing 20–25 g within 18 h). This comparatively non-toxic fraction still has a remarkable action on Yoshida sarcoma cells.

The interference microscope has been used to observe changes in cell membrane permeability leading to loss of cytoplasm from these cells and from various normal cells. The effects are similar to those examined in the familiar phenomenon of lysis of erythrocytes leading to the loss of haemoglobin and appearance of cell ghosts. Interference microscopy, because it is so sensitive to small mass changes, makes it possible to examine the lysis of tissue cells<sup>2</sup>. Results obtained using Yoshida rat sarcoma cells and on various normal rat cells suspended in Tyrode's solution and in rat serum are shown in Table 1. The erythrocytes, lymphocytes from lymph nodes and bone marrow cells were all observed as suspensions prepared without the use of chelating agents or trypsin. The intestinal mucosa cells were obtained as small areas of epithelial sheets containing 20–50 cells, also prepared without the use of chelating agents or trypsin. The mucosa cells were therefore obtained in their natural sheet-like state and would be in a very similar situation to that occurring *in vivo*. It can be seen from Table 1 that this fraction of low animal toxicity is extremely toxic for tumour cells and is highly selective in its action. Serum has a protective action on the normal cells but has little effect on the sensitivity of the tumour cells.

These observations support the view that changes in the cell membrane of tumour cells are of a characteristic nature. The low adhesiveness and high mitotic rate of the tumour have not been brought about by membrane

Table 1. CYTOTOXICITY OF A COBRA VENOM FRACTION

Cell type (Rat cells)	Dilution of a solution of 1 mg/ml. protein required to produce 50% of cell lysis in 0.5 h	
	Tyrode	Rat serum
Y. sarcoma	1/128	1/128–1/64
Red blood cells	1/64–1/32	1/4
Lymphocytes	1/16–1/8	1/4
Bone marrow	1/32	1/2
Intestinal mucosa	1/2	1/2

properties similar to rapidly dividing normal cells such as intestinal mucosa, nor are they similar to those of relatively non-adhesive erythrocytes, lymphocytes or bone marrow cells. Ambrose and Easty<sup>2</sup> obtained evidence for slight selectivity using whole venom (Russell's viper) in comparative investigations of tumour and normal cells in culture.

Preliminary *in vivo* investigations using this fraction have been quite encouraging, and several animals have been cured of Yoshida ascites tumours; but *in vivo* effects involve problems connected with blood supply to the tumour, rate of elimination of the agent, etc. Whatever the final success obtained with this fraction *in vivo*, the experiments described here on lytic action indicate that the necessary specificity of a structure is present on the tumour cell surface in this case. It may be possible to exploit this by the use of biological macromolecules containing the required properties in their amino-acid, sugar or nucleotide sequence as carcinolytic agents.

We thank Prof. A. Haddow and Dr. A. R. Gopal-Ayengar for their advice. One of us (E. J. A.) also thanks the U.K. Ministry of Overseas Development and the Atomic Energy Commission, Government of India, for their support (Colombo Plan).

## Reversal of Selective Toxicity of (-)- $\alpha$ -Lipoic Acid by Thiamine in Thiamine-deficient Rats

INTRAPERITONEAL injection of ( $\pm$ )- $\alpha$ -lipoic acid has been reported to be toxic to thiamine-deficient rats<sup>1</sup>. Development of the toxic effect was prevented by simultaneous injection of 100  $\mu$ g of thiamine hydrochloride. It was also noticed that ( $\pm$ )- $\alpha$ -lipoic acid, unlike neopyrithiamine, had no effect on thiamine excretion. The toxicity of ( $\pm$ )- $\alpha$ -lipoic acid to thiamine-deficient rats therefore could not be related to the depletion of the thiamine reserves present in the organs of thiamine-deficient animals. Obviously, the results obtained from the use of the racemic form of lipoic acid could not reveal whether both or one of the isomers had been responsible for the toxic effects in the deficient animals. In order to clarify the relative toxicity of the isomers of lipoic acid in thiamine-deficient rats, the experiments were repeated with the natural and unnatural isomers of  $\alpha$ -lipoic acid. The preparation of pure (+)- $\alpha$ -lipoic acid was accomplished from (+)-6,8-dichlorooctanoic acid (-)-ephedrine salt<sup>2</sup>. However, the (-)- $\alpha$ -lipoic acid was found to be contaminated with 15-20 per cent of the dextro-rotatory enantiomorph<sup>3</sup>. Therefore, the pure (-)- $\alpha$ -lipoic acid was synthesized from the purified (-)-6,8-dichlorooctanoic acid (+)-ephedrine salt. This was obtained after converting a sample of (-)-6,8-dichlorooctanoic acid (-)-ephedrine salt into the (+)-ephedrine salt. (The (-)-6,8-dichlorooctanoic acid (-)-ephedrine salt was generously supplied by Dr. W. J. Wayne of Du Pont.)

In the experiments with the various forms of lipoic acid, 20 mg/kg of  $\alpha$ -lipoic acid was administered intraperitoneally to thiamine-deficient Sprague-Dawley rats of 100-150 g average weight. When the animals developed the 'acute stage' of polyneuritis<sup>4</sup>, they were divided into

Table 1. TOXICITY OF (-)- $\alpha$ -LIPIC ACID AND ITS EFFECT ON URINARY THIAMINE EXCRETION IN THIAMINE-DEFICIENT RATS

Compound	Mortality of deficient rats (%)	Urinary thiamine* in 3 days $\mu$ g	%
( $\pm$ )- $\alpha$ -Lipoic acid	75 (18)	—	—
( $\pm$ )- $\alpha$ -Lipoic acid + Thiamine (250 $\mu$ g)	0 (10)	69	28
(+)- $\alpha$ -Lipoic acid	40 (16)	—	—
(+)- $\alpha$ -Lipoic acid + Thiamine (250 $\mu$ g)	10 (10)	64	26
(-)- $\alpha$ -Lipoic acid	80 (16)	—	—
(-)- $\alpha$ -Lipoic acid + Thiamine (250 $\mu$ g)	20 (10)	70	28
Neopyrithiamine	27 (10)	—	—
Neopyrithiamine + Thiamine (250 $\mu$ g)	0 (6)	150	60
Isotonic saline + Thiamine (250 $\mu$ g)	0 (6)	60	24

The animals in the various groups received i.p. injection of 20 mg/kg of the different lipoic acids or 5 mg/kg of neopyrithiamine. \*In some groups when the urinary thiamine excretion fell below detection, the animals received 250  $\mu$ g of thiamine hydrochloride followed by injection of lipoic acids, or neopyrithiamine or saline. No. of animals is given in brackets.

subgroups as shown in Table 1. After the daily collection of urine, the animals were fed in the morning and the food was withdrawn. When the urinary thiamine values fell below detection, some of the animals in each group received 250  $\mu$ g of thiamine HCl intraperitoneally, followed by i.p. injection of lipoic acid or neopyrithiamine. The urine samples were 24-h collections. They were collected for three days and were daily analysed for thiamine excretion. The values in Table 1 represent the total thiamine excreted in three days. Earlier it was established<sup>1</sup> that the 20 mg/kg ( $\pm$ )- $\alpha$ -lipoic acid corresponded to 1/4 of the  $LD_{50}$  dose. Since intraperitoneal injection of isotonic saline was not lethal to the thiamine-deficient animals, it is apparent that the mechanical effect of injection *per se* is of no consequence. Again it is obvious from Table 1 that the simultaneous injection of thiamine and lipoic acid prevented death, which ordinarily occurred when lipoic acid was administered alone to the deficient rats. Interestingly, (-)- $\alpha$ -lipoic acid seemed to be extremely toxic to thiamine-sufficient animals had not produced any undue physiological effects. As a further confirmation of earlier findings<sup>1</sup>, it has been demonstrated that a single intraperitoneal injection of 250  $\mu$ g of thiamine hydrochloride followed by the injection of any of the lipoic acids does not lead to increased urinary thiamine excretion during the succeeding 72 h. The results show that neither the racemate nor either of the isomers of  $\alpha$ -lipoic acid had any effect on thiamine mobilization while intraperitoneally administered neopyrithiamine (5 mg/kg) produced significant increase in thiamine excretion. No significant difference between the amounts of thiamine excretion before and after lipoic acid treatment could be observed in the experiments with thiamine-sufficient rats. At present the marked toxicity of (-)- $\alpha$ -lipoic acid is interpreted as an interaction between the thiaminethiol of the thiamine and (-)- $\alpha$ -lipoic acid, yielding a toxic intermediate in the brain possibly through a heteromeric interaction between thiamine and sulphydryl groups as suggested by Banhidi<sup>4</sup>. Such interaction could yield a toxic intermediate which would not only tie up thiamine reserves in the brain but also could cause the displacement of the natural isomer of  $\alpha$ -lipoic acid from the sites of enzymatic decarboxylation of  $\alpha$ -keto acids. The search for existence of such an intermediate is proposed to be undertaken with the aid of labelled isomers of  $\alpha$ -lipoic acid.

## HAEMATOLOGY

# Role of Properdin, 0° Factor, Polyinosinic Acid, and Thrombin in the Haemolysis of Paroxysmal Nocturnal Haemoglobinuria Erythrocytes

ABSORPTION of serum at 15° C with zymosan renders the serum deficient in properdin and destroys the capacity of such RP serum to haemolyse paroxysmal nocturnal haemoglobinuria erythrocytes (PNHE)<sup>1</sup>. Absorption of serum with zymosan at 0° C does not remove properdin, but does remove a zymosan specific fraction ('0° factor'), so that on incubation with fresh zymosan at 15° C properdin is no longer affected<sup>2</sup>. Recent work in this laboratory has defined the PNHE haemolytic system as one dependent on fluid phase complement (C') activation resulting in red cell membrane destruction as a result of direct attack by C'3 sub-components<sup>3</sup>. C'1 esterase or C'1 activators have been shown to enhance PNHE lysis and in addition certain C'1 activators such as polyinosinic acid (poly I) may initiate the haemolysis of normal human erythrocytes (NHE), presumably by similar fluid phase complement reactions<sup>4</sup>. Thrombin has also been shown to enhance PNHE lysis, but the mechanism of this enhancement has been the subject of considerable controversy. The observations shown in Table 1 were designed to assess the relative role of properdin and '0° factor' in native and poly I enhanced PNHE lysis, and to compare the stimulating effect of poly I on PNHE haemolysis with the ability of thrombin ('Thrombin', bovine, Upjohn Co., Kalamazoo, Mich.), both absorbed with NHE and unabsorbed, to enhance PNHE lysis.

Table 1. EFFECT OF PROPERDIN AND '0° FACTOR' DEPLETION ON POLY I-ENHANCED HAEMOLYSIS OF PNHE RED CELLS; COMPARISON OF POLY I EFFECT WITH THROMBIN EFFECT

Addition to test serum	Percentage haemolysis					
	Normal serum	pH 7.6 0° super-natant serum	RP serum	Normal serum	pH 6.5 0° super-natant serum	RP serum
Saline (0.1 ml.)	14	14	1	51	54	2
Poly I—1 $\mu$ mole P	56	56	15	81	81	64
Thrombin—50 U	66	66	63	73	73	68
Absorbed thrombin—50 U	27	24	1	53	53	28

The haemolytic test system consisted of 1 ml. of the appropriate serum, acidified where indicated with 0.3 N HCl, 0.05 ml. of a 20 per cent suspension of PNHE in 0.15 M NaCl, and 0.1 ml. of 0.15 M NaCl or 0.1 ml. of the appropriate material dissolved in 0.15 M NaCl, added in the order mentioned. After incubation at 37° for 30 min under oil, the tubes were centrifuged and read at 540 m $\mu$  in a Zeiss PMQ II spectrophotometer against the appropriate serum blank.

Removal of '0° factor' from serum does not affect the ability of serum to support PNHE haemolysis under any of the experimental conditions cited. Removal of properdin, on the other hand, does inhibit the capacity of serum to support PNHE haemolysis at both pH 7.6 and 6.5. The ability to haemolyse PNHE can be restored to RP serum by the addition of poly I; the latter stimulates PNHE haemolysis in RP serum much more effectively at pH 6.5 than at pH 7.6, but at neither pH does poly I-enhanced haemolysis proceed as well as in normal serum. Absorption of thrombin with NHE diminishes greatly its ability to stimulate PNHE cell lysis. Addition of NHE-absorbed thrombin to normal serum at pH 6.5 does not result in significant enhancement of PNHE haemolysis. The latter observation agrees with those of Hinz<sup>5</sup>, but is at variance with the experience of two other groups<sup>6,7</sup>, who have found residual capacity for PNHE acid haemolysis stimulation in thrombin which has been exhaustively absorbed by NHE. More in keeping with these latter reports, however, we have found that absorbed thrombin can provoke moderate enhancement of PNHE haemolysis in normal serum at pH 7.6, and can partially restore haemolytic capacity to RP serum at pH 6.5. Removal of

properdin from serum diminishes, but does not completely abolish, the ability of poly I to provoke haemolysis of NHE at pH 6.5 (ref. 4).

Properdin and zymosan-specific '0° factor' are not required for poly I-induced haemolysis, although poly I-induced haemolysis is reduced somewhat in RP serum. '0° factor' is also not required for native PNHE haemolysis. Viewing properdin as related intimately to the recognized components of C' (ref. 8), and recognizing the peculiar affinity of zymosan for C'3 (ref. 9), one could speculate that properdin is, in fact, a sub-component of C'3. Such a possibility has been reinforced by our recent observations that the intermediate complex, PNHE<sub>1</sub>, formed by exposure of PNHE to partially purified human  $\beta_{12}$  globulin (C'3a), is highly susceptible to haemolysis in RP serum in the presence of Na<sub>2</sub>HEDTA (ref. 3). Bearing in mind the concepts recently developed on the special relationship of late-acting C' components to PNHE haemolysis<sup>8,9</sup>, it is conceivable that partial depletion of such a C'3 sub-component might critically affect a haemolytic system dependent on threshold amounts of activated fluid phase, late-acting C' components (native PNHE haemolysis); might partially, but not completely, inhibit a haemolytic system capable of activating more efficiently residual fluid phase late-acting C' components (poly I-induced haemolysis); and might inhibit only slightly, if at all, a haemolytic system capable of activating and utilizing the residue of such a factor with great efficiency at the cell membrane (classical immune haemolysis).

Most observers agree that much of the ability of commercial bovine thrombin to enhance PNHE haemolysis is attributable to the presence of red cell hetero-antibodies<sup>8-10</sup>. However, our observations, in agreement with those of Jenkins *et al.*<sup>6</sup> and Crosby and Benjamin<sup>7</sup>, demonstrate that even after extensive absorption with human red cells, such bovine thrombin is still capable, under certain conditions, of enhancing PNHE haemolysis. Jenkins *et al.* have clearly shown that thrombin *per se* is not involved in this enhancement; since the factor in question is heat stable, they conclude that it is non-absorbable antibody<sup>6</sup>. On the basis of the mechanisms discussed in this communication, however, this enhancing factor could be either a substance which, like poly I, is capable of activating C'1, or the bovine counterpart of one of the heat stable C'3 sub-components of guinea-pig serum (C'3c, C'3b) (ref. 10). That at least one of the bovine C'3 sub-components can function in a heterospecific C' system has been demonstrated by Lincoff and Nishioka, who used bovine plasma as a rich source of C'3d (ref. 10).

# PATHOLOGY

## Function of Collagen: Blood Pressure in Lathyrotic Rats

COLLAGEN constitutes approximately one-third of the body protein in mammals. While its significance in maintaining form is obvious, little is known of its possible role in physiological processes. Discovering functions of collagen would be of particular importance in regard to ageing. Physical properties of collagen change markedly with age, presumably because of increased cross-linkages, but these changes have not been related to the decrease in efficiency of physiological processes characteristic of ageing. The changes in collagen with age and their possible significance have recently been reviewed<sup>1</sup>.

Because of its distribution in and around blood vessels, collagen would be expected to influence haemodynamics. The production of lathyrism in laboratory animals by the administration of certain nitriles provides a system in which the role of collagen in blood vessel reactivity can be studied. In lathyrism, maturation of collagen by cross-linking is defective, and affected animals have less than the normal amount of mature collagen<sup>2</sup>. The present work was based on the supposition that if mature collagen influences the reactivity of blood vessels, differences in blood pressure between control and lathyrotic animals should be detected when animals are treated with norepinephrine.

Male Holtzman rats weighing approximately 110 g were used. Three animals were kept as controls and four were given  $\beta$ -amino-propionitrile fumarate intraperitoneally, one mg per g body wt. per day, as a 20 per cent solution in 0.15 M NaCl. After 8 days treatment the animals were anaesthetized with 0.2 ml. 'Nembutal' per 100 g body wt. and heparinized polyethylene catheters (gauge No. 50) were secured in femoral arteries and veins. Each arterial catheter was attached to a mercury manometer and mean blood pressures were read directly. After baselines were established, each animal was given, in the venous catheter, 0.1 ml. 5 per cent dextrose containing 0.1  $\mu$ g norepinephrine. All the control rats showed a greater rise in blood pressure than the lathyrotics (Fig. 1). The mean maximum blood pressure rise for the controls was 49.3 mm Hg; that for the lathyrotics, 35.0.

A possible explanation for this observation is that mature collagen fibres are oriented in such a way that, when arterioles constrict, they stabilize the vessels in their new configuration and maintain pressure. Without collagen support, the smooth muscle cells cannot remain adequately contracted in opposition to the force exerted by the blood. Similar conclusions concerning the role of

collagen fibres in the aorta were arrived at on morphological grounds by Wolinsky and Glagov<sup>3</sup>. If future work indicates that lathyrism causes significant changes in smooth muscle cells, other explanations may be more reasonable.

## Growth-promoting Effect of Chondroitin Sulphate on Solid Ehrlich Ascites Tumour

In the course of studying the interaction between connective tissue and cancer cells, I found that chondroitin sulphate promoted the growth of solid Ehrlich ascites tumour. Tumour cells used in this study were of Ehrlich hypotetraploid stock (Kawiwara<sup>1</sup> 4N) which was maintained intraperitoneally in SM male mice.

The first series of experiments was made with the chorioallantoic membrane (CAM) of the White Leghorn chick embryo. A disk, 8 mm in diameter and 3 mg in weight, made of 'Spongel' (Yamanouchi Seiyaku Co. Ltd., Tokyo), was soaked with solutions of various concentrations of chondroitin sulphate *O* (av. mol. wt., 50,000; Kaken Yakukako Co. Ltd., Tokyo). For controls, 0.85 per cent saline was used. 0.01 ml. of Ehrlich tumour ascitic fluid containing  $5 \times 10^4$  cells was dropped on to the disk placed in a Petri dish. Then the disk, which contained both tumour cells and the solution, was implanted on the CAM of the chick, on the 6-7th day of its incubation. The embryos were killed on the 8th day after tumour implantation, and the solid tumour developed in and around the 'Spongel' disk on CAM was excised and weighed.

The effect of chondroitin sulphate on tumour growth on CAM is shown in Table 1. A statistically significant increase in weight of tumour tissue was noted in all the chondroitin sulphate-treated groups. The chondroitin sulphate absorbed in the 'Spongel' disk was demonstrated in the excised tumour mass as a metachromatic spot on the filter paper.

The second series of experiments were made with SM male mice about 100 days old, fed with standard pellet diet and water *ad libitum*. One ml. of 2 per cent chondroitin sulphate *O* solution was subcutaneously injected into the right flanks of the mice, immediately followed by inoculation of 0.1 ml. of the Ehrlich tumour ascitic fluid

Fig. 1. Mean blood pressures of control and lathyrotic rats as a function of time. Arrow indicates time of intravenous injection of norepinephrine. —, Controls; ----, lathyrotic rats

containing  $5 \times 10^6$  cells into the same site. In the control group, 1 ml. of 0.85 per cent saline was injected before the tumour inoculation. The animals were killed on the 8th day after tumour inoculation, and solid tumours developed in the subcutaneous space of mice were excised and weighed. As shown in Table 2, the average tumour weight in the chondroitin sulphate-treated groups was  $2,008 \pm 120$  mg, whereas it was  $1,067 \pm 73$  mg in the control, and the difference is statistically significant.

In other experiments, the effects of heparin and collagen were tested on the OAM of chick embryos, but no significant promoting effect was observed. Experiments are now being made on the effect of human umbilical cord extract and hyaluronic acid.

Ozzello *et al.*<sup>3</sup> demonstrated the growth-promoting activity of acid-mucopolysaccharides on a strain of human mammary carcinoma cells *in vitro*, and I<sup>4</sup> have also reported that chondroitin sulphate solution enhanced the growth of subcutaneously inoculated Brown-Pearce rabbit carcinoma.

Rogers<sup>5</sup> reported "water retention, rate of diffusion, macroionic function, lubrication and others" as the physical functions of acid-mucopolysaccharides. It is my opinion that they may have some action which preserves the inoculated tumour cells, which may be due to the negative electric charge of acid-mucopolysaccharide, and its viscosity.

Vasiliev<sup>6</sup> showed that formation of new connective tissue around neoplasms may be important in many cases for invasive growth of malignant cells, and the present experiments, I believe, appear to indicate that the proliferation of new connective tissue which produces acid-mucopolysaccharides is favourable to the growth of cancer cells.

I thank Prof. H. Tauchi for his advice.

### Effect of Aerobic Pre-Incubation on Glycolysis in Resting and Proliferating Liver Cells

A SHORT aerobic pre-incubation period before the onset of anaerobiosis greatly stimulates the rate of anaerobic glycolysis in slices of tissue. This fact, discovered by Rosenthal and Lesnitsky many years ago<sup>1</sup>, has later been confirmed<sup>2-4</sup>; but the mechanism of action of the previous incubation remains up to now largely unexplained.

In the course of work on the events connected with the glycolytic stimulation by previous aerobiosis, we have examined the occurrence of this effect in various tumours, as well as in diverse injured tissues; in this communication, work on Yoshida ascites hepatoma cells, non-tumour actively proliferating liver cells, and normal liver is described.

Glycolysis has been measured manometrically in a conventional Warburg apparatus at 37° C. The compo-

(5) 17.6	17.3	-0.3	(5) 44.1	44.2	+0.1

sition of the medium is given in Table 1. For the sake of uniformity, glucose was added in all cases, since glycolysis in tumour cells is strictly dependent on the presence of glucose in the medium.

Pre-incubation was carried out in 95 per cent oxygen + 5 per cent carbon dioxide, for 15 min; the gas was then replaced with 95 per cent nitrogen + 5 per cent carbon dioxide and readings were begun 10 min after the end of aerobic pre-incubation. Glycolysis after pre-incubation is defined as 'stimulated glycolysis', while glycolysis without pre-incubation is called simply glycolysis or 'basal glycolysis'.

Yoshida ascites hepatoma cells were collected from albino rats 8 days after intraperitoneal transplantation. The ascitic fluid was diluted with cold saline and centrifuged for 5 min at 500 g in the cold; the cells were then washed twice in cold saline and finally suspended in the medium used for the experiments.

The amount of cells in each Warburg vessel gave a dry residue (corrected) of about 10 mg.

Livers were sliced by hand with a razor. Foetal livers were taken during the last four days before birth; the slices from several foetuses of the same litter were pooled together, and distributed at random in the vessels. Regenerating livers were taken from fed rats, 6 days after partial hepatectomy. Normal livers were from fed rats.

In normal livers from fed adult rats the pre-incubation in oxygen brings about a consistent increase in the rate of glycolysis. The stimulation, defined as the difference between stimulated and basal glycolysis, is rather variable, but occurs in all cases. The particular features of stimulated glycolysis in normal liver cells are now under investigation.

In regenerating rat liver slices, 6 days after hepatectomy, basal glycolysis is not particularly high, but stimulation is reduced, in partial agreement with previous results<sup>5</sup>.

On the contrary, foetal rat liver displays a high basal glycolysis; but this is in no way increased by aerobic pre-incubation. The same holds true for hepatoma cells, which show an even higher rate of basal glycolysis.

The comparison of the behaviour of the glycolytic stimulation in these various tissues rests on the assumption that they are basically composed of the same cellular types, living and growing in their own peculiar ways. However, slices of normal, regenerating and foetal livers can contain different amounts of connective tissue, while Yoshida ascites hepatoma is a population of pure cells. Besides, in foetal liver slices, cells involved in haemopoiesis are found side-by-side with parenchymal liver cells<sup>6</sup>. If, as is generally done, the tissues are considered sufficiently comparable, the problem of the failure of aerobic stimulation in foetal and neoplastic liver cells can be discussed.

It may be suggested that a higher glycolytic activity in liver cells is attained only under the influence of some factors formed in the normal tissue—but not in foetal or tumour cells—during aerobiosis. Alternatively, it could be said that aerobiosis removes some limiting factors which are present in normal tissue but not in foetal and tumour cells, the glycolysis of which is already fully 'released'.

In view of our present knowledge on the glycolysis of tumours, and on the basis of results which will be fully reported elsewhere, the second hypothesis seems more probable. The existence of mitochondrial factors which interfere with glycolysis in normal cells and which are lacking in cancer cells has been shown by Neifakh *et al.*<sup>7</sup>. Moreover, it should be noted that deficiency in the number of mitochondria seems to be a feature common to foetal and cancer cells.

## IMMUNOLOGY

### Potentiating Effect of Neonatal Thymectomy on X-ray-Induced Intercapillary Glomerulosclerosis

X-IRRADIATION (150–900 rads) accelerates the course of intercapillary glomerulosclerosis (IGS), a naturally occurring progressive ageing process in mice, rats and hamsters<sup>1</sup>. This acceleration effect occurs only in kidney tissue which is directly irradiated and is preceded by a latent period, the duration of which is dependent on age of the animal at exposure.

There is some reason to think that an immune mechanism might be involved in the pathogenesis of IGS. This is suggested by the progressive nature of the renal lesions, by the presence of  $\gamma$ -globulin at the site of the glomerular lesions<sup>2</sup>, its similarity to changes observed in experimental immune disease of the kidney<sup>3</sup>, and the occurrence of a latent period before cytological changes are demonstrable. The results of neonatal thymectomy on the course of X-ray-induced IGS are reported in this communication.

Swiss-Webster mice were taken from their mothers within 24 h of birth, kept at room temperature for at least 30 min, and then given a single whole-body dose of 375 rads of 250-kV X-ray (42–45 rads/min). Groups of five animals, selected at random, were then returned to mothers chosen at random. In the case of animals to be thymectomized, the returned litter size was eight to allow for the large mortality following operation. Thymectomy was done within 24 h of irradiation by means of sternal exposure and suction. The wound was sutured and the animals placed under a heat lamp for 1 h before they were returned to foster mothers. Cannibalism was largely prevented by trimming the teeth of the mothers just prior to return of offspring. Animals were weaned at age 28 days, then housed in small aluminium pens with wood shavings, 1–4 animals per pen, and fed a commercial pellet ration.

All survivors at age 28 days were skin grafted. Tail-skin from a one-month-old (OSTBL/8By  $\times$  BALB/cBy)  $F_1$  female mouse was transplanted to the tail of the host as described by Bailey and Usama<sup>4</sup>, but modified by eliminating antibiotics and substituting several folds of masking tape for collodion and wound clips to hold the glass tube in position. Recorded observation of graft survival was begun on the fifth day after grafting and continued at two-day intervals.

Animals were killed by cervical dislocation. The histological methods for preparing the kidneys, involving the use of Tellysniak's fixative and the Rinehart-Abdul-Haj colloidal iron-cochineal stain<sup>5</sup>, and for grading the

\* S.E.

degree of IGS were as described previously<sup>6</sup>. Lymphatic and thymic tissues were also stained with haematoxylin and eosin, pyronin-methyl green and Giemsa. All residual tissue in the thymic area of operated animals was examined microscopically; unsuccessfully thymectomized animals were discarded. The animals were killed in two series; the first, an exploratory one, examined at an average of 47 days of age and the second at an average of 67 days. Grades were established to represent the mean values of all animals in each group. For each kidney, the grades were derived by totalling values of 0–4 for each of 25 glomeruli based on histological criteria of degree of change.

In agreement with previous findings<sup>6</sup>, there was a decided effect of X-irradiation on the grade of IGS. The difference of mean IGS grades of irradiated and non-irradiated groups with or without thymectomy was highly significant ( $P < 0.005$ ). The difference between the X-irradiated group and the X-irradiated-thymectomized group was also statistically significant in both the first ( $P < 0.025$ ) and the second ( $P < 0.005$ ) series killed. Histological characteristics of the kidney lesions in these latter two groups were the same, differing only in degree. The difference between the non-irradiated-thymectomized group and either of the sham-control groups was not significant.

Examination of the spleen showed lymphoid depletion of the white pulp in all thymectomized animals. Irradiation alone or combined with thymectomy did not result in measurable effect on the degree of lymphoid depletion. Of significance was the presence of marked concentrations of pyroninophilic cells in the reticulum about the central arteries of the white pulp and their finer branches in all animals which were completely thymectomized at birth. Many of these showed characteristics of mature plasma cells. The lymph nodes also showed large numbers of pyroninophilic cells in the lymph cords and marked depletion of lymphocytes in the cortex.

The number of mice graft-tested in each group is given in Table 1. There were three technical failures. Thymectomy with or without X-irradiation significantly increased the number of surviving grafts ( $P < 0.001$ ) in  $\chi^2$  test. X-irradiation with or without thymectomy had no apparent effect.

From these observations it is clear that neonatal thymectomy potentiates the effect of X-rays on the development of IGS. The nature of the lesion was unchanged and there was no indication of a superimposed inflammatory process either in the irradiated or non-irradiated thymectomized animals. Wasting disease with associated renal disease, such as described by DeVries *et al.*<sup>7</sup>, had not developed in our strain of animals at the time of killing. One may speculate whether the thymus has some tissue regulatory function, a deficiency of which may lead to acceleration of degenerative changes, or whether IGS is a manifestation of an immune reaction. With respect to the former, no pertinent evidence appears to be available. With respect to the latter, there is indication that the immune mechanism is altered in our animals following neonatal thymectomy, as shown by increased tolerance to skin grafts in confirmation of results of other investigators<sup>8–10</sup>. There are some recent data<sup>11</sup> indicating that neonatal thymectomy may also evoke

auto-immunity. The presence of large aggregates of pyroninophilic cells in the spleen and lymph nodes in our neonatally thymectomized animals, and similar observations in rats by Wakeman *et al.*<sup>12</sup>, also suggest this possibility, although as yet we have no proof of immune competence of these cells. Whether auto-immunity plays a part in the pathogenesis of radiation-induced lesions of the kidney remains to be demonstrated by definitive immunological examinations. The present findings warrant further investigations of this possibility.

We thank Dr. H. I. Kohn for his help in the experiment. This work was supported by the U.S. Atomic Energy Commission.

### Antigenic Properties of Burnt Skin

ON surveying the literature pertaining to this subject, it was found that workers in the Eastern European countries<sup>1</sup> maintain that the use of convalescent serum in burnt patients is of considerable therapeutic value due to a hypothetical antibody to burnt skin<sup>2</sup>. Workers in the Western world<sup>3-7</sup> in the same field have been unable as yet to prove the existence of such an immunological mechanism and have claimed that any antibody demonstrated so far has been one produced by bacteria, thus not specific to burnt tissue.

Table 1. ANTIGEN-ANTIBODY REACTIONS WITH SERA OF RABBITS IMMUNIZED WITH VARIOUS PORTIONS OF BURNED SKIN, BY DIFFERENT IMMUNOLOGICAL SEROLOGICAL PROCEDURES

\* Antigens: No. 1, sterile skin; No. 2, skin exposed in oven to 120° C for 20 min; No. 3, skin exposed to burning over gas flame.  
† The highest dilution of immune sera which gave a visible precipitation.  
‡ The highest dilution of immune sera which gave haemagglutination sensitized with various antigens by tanned erythrocytes or erythrocytes linked with 4a-diazotized-benzidine (BDB).

A pilot experiment on this subject was conducted, using several immunological procedures. Three groups of rabbits were immunized with antigens, prepared from: (1) a portion of sterile skin from a freshly killed rabbit; (2) a portion of skin of the same rabbit after having been exposed to a temperature of 120° C in an oven for 20 min; (3) a portion of skin of the same rabbit, after having been exposed to burning over a gas flame. Six rabbits were immunized; A and B, with antigen 1; C and D, with antigen 2; E and F, with antigen 3.

The antigens were prepared by homogenizing the three portions of skin in a Waring blender, with subsequent extraction in normal saline. The antigens were defatted with ether during 24 h. Sterility was confirmed by culture.

The sera obtained from the rabbits after repeated immunization for a period of about 6 weeks were studied by several methods, such as haemagglutination and haemagglutination inhibition tests (BDB and tannic acid method), precipitin tests, gel-diffusion and passive cutaneous anaphylaxis in the guinea-pig. The results are summarized in Tables 1 and 2. These results show that burnt skin has antigenic properties, producing antibodies in rabbits, different from normal skin. It has to be pointed out that there are still considerable difficulties as to the reproducibility of the experiments, their cross-reactivity among the various portions of the skin, etc. Although antibodies in rabbits have been produced from burnt skin, the specificity of these antibodies, and their relationship to human burns, has to be investigated in greater detail.

### HISTOLOGY

#### Venous Output of Lymphocytes from the Thymus

FOLLOWING the extensive quantitative investigations of Kindred<sup>1,2</sup> on the frequency of mitosis in different lymphatic organs, it has been known that intense lymphocytopoiesis occurs in the thymus. This observation has repeatedly been confirmed by other workers, using

\* †, See Table 1

the same as well as other methods for demonstration of lymphocytopoiesis<sup>3</sup>.

The fate of these lymphocytes has been a matter of controversy. Kindred suggested that they leave the thymus, but he presented no direct proof of this assumption. Some indirect evidence has since accumulated, suggesting migration of lymphocytes from the thymus into the blood, and seeding of these thymic lymphocytes into other lymphatic organs<sup>4</sup>. Among this indirect evidence can be mentioned observations in sections of the thymus, suggesting diapedesis of lymphocytes into blood vessels<sup>5</sup>. The direction of such diapedesis cannot, however, be judged from sections and, in a recent review, Sainte-Marie and Leblond<sup>6</sup> pointed out "that no route has been demonstrated by which thymic lymphocytes might leave the organ". Gowans, Metcalf and others summarized the question in the same way<sup>7</sup>, that is that it has not been conclusively demonstrated that thymic lymphocytes do, in fact, migrate from the thymus. The lack of direct evidence proving that lymphocytes leave the thymus, is also consistent with the theory that the lymphocytes formed in this organ remain there, die, undergo cytotoxicity and perhaps release nucleic acid or some other non-cellular factors into the circulation.

Three routes for migration of lymphocytes from the thymus are possible—lymphatic channels, perivascular lymphatic spaces and blood vessels. It is generally claimed that the thymus contains few lymph vessels. The role of the perivascular lymphatic channels is not known, and it may be that they do not continue outside the organ. The most probable route is the blood vessels, and these have, in fact, most often been presumed to receive migrating thymic lymphocytes. No studies on the lymphocyte content of the efferent blood vessels from the thymus seem to exist in the literature.

Growing male guinea-pigs (200–300 g) were anaesthetized with sodium nembutal, i.p., and their thymus glands dissected out. Blood samples were taken from the carotid artery near the origin of the thymic arteries, and from the efferent thymic veins. In some animals, blood was also taken from the femoral veins. 25 mm<sup>3</sup> of blood was diluted with 475 mm<sup>3</sup> of Tolisson's solution (containing methyl violet, for staining the white blood cells). Blood smears were prepared simultaneously, and stained with Giemsa stain. The number of white cells per mm<sup>3</sup> was counted in a Bürker counting chamber—288 squares (corresponding to 0.00825 mm<sup>2</sup> each) being counted for each sample. The percentage of lymphocytes was calculated from the smears, 200 white cells being counted.

The number of lymphocytes per mm<sup>3</sup> and the percentage of lymphocytes were (mean  $\pm$  S.E.):

	% Lympho- cytes	No.	Lympho- cytes/mm <sup>3</sup>	No.
Afferent thymus blood (carotid artery)	60.7 $\pm$ 2.5	25	2,323 $\pm$ 233	25
Efferent thymus blood (thymic veins)	69.0 $\pm$ 2.2	25	3,496 $\pm$ 567	10

The difference between the percentage of lymphocytes in afferent and efferent thymic blood is significant at the 0.05 level ( $t = 2.55$ ). The difference between the absolute number of lymphocytes per mm<sup>3</sup> blood is not significant ( $t = 1.82$ ). The percentage of lymphocytes and the number of lymphocytes per mm<sup>3</sup> in the femoral vein blood were approximately the same as in the blood from the carotid artery. This implies that similar increases in percentage and number of lymphocytes were demonstrated in efferent thymic blood also when compared with femoral vein blood.

In view of differences between the animals with respect to white cell count and percentage of lymphocytes, less variation is obtained if the calculations are based on mean differences between the lymphocyte content of samples from the thymic veins and from the carotid artery or femoral vein in the same animal. Such calculations gave the following mean differences (abbreviations:

TV, efferent thymic blood (from thymic veins); CA, blood from the carotid artery; FV, blood from the femoral vein):

Differences in percentage of lymphocytes (mean $\pm$ S.E.):	
TV-CA:	8.36 $\pm$ 2.14, No. = 25, $P < 0.001$
TV-FV:	11.85 $\pm$ 3.14, No. = 18, $P < 0.001$
Differences in number of lymphocytes per mm <sup>3</sup> (mean $\pm$ S.E.):	
TV-CA:	1,025 $\pm$ 233, No. = 9, $P < 0.01$
TV-FV:	784 $\pm$ 204, No. = 8, $P < 0.05$

The results demonstrated an increased content of lymphocytes in the blood leaving the thymus.

## RADIOBIOLOGY

### Effect of Cysteamine, Cyanide and High-pressure Oxygen on Splenic Oxygen Tension and Sulphydryl Content

The mechanism of action of cysteamine, one of the most potent compounds which protects against ionizing radiation, remains obscure.

Many of the less effective radioprotective compounds have now been reported to exert their action in the intact animal by causing tissue hypoxia. Thus adrenaline, histamine, chlorpromazine and dinitrophenol all lower tissue oxygen tension<sup>1,2</sup> and their effect is potentiated by lowering the oxygen concentration in the gas breathed by the animal, and inhibited by breathing oxygen at pressures above normal<sup>3,4</sup>.

Cysteamine, however, produces little or no change in tissue oxygenation in the spleen of animals breathing air<sup>5</sup> and the radioprotection shown by this compound is only slightly reduced when rats are irradiated during exposure to 5 atmospheres of oxygen<sup>6</sup>. The combination of CN<sup>-</sup> plus cysteamine pretreatment slightly reduces the radioprotection of cysteamine alone and the combined treatment with cyanide plus oxygen at 4–5 atmospheres further counteracts cysteamine protection against X-rays (van den Brank, unpublished observations). Similar effects are seen with 5-hydroxytryptamine and cysteamine<sup>4</sup>.

It was thought that CN<sup>-</sup>, by reducing oxygen consumption by the cells, may potentiate the action of high oxygen pressures in raising tissue oxygen tensions. This was tested using the oxygen electrode technique for the measurement of tissue pO<sub>2</sub> in rat spleen, the latter tissue being a radiosensitive locus. Canberra black male rats, 160–190 g weight, were used in all experiments. The estimation of splenic pO<sub>2</sub> with 60  $\mu$  bare-tipped gold electrodes has been described in detail<sup>7</sup> and the apparatus for pressurization was the same as that used in previous experiments<sup>8</sup>.

The results of splenic pO<sub>2</sub> measurements in control rats breathing air at 1 atmosphere or oxygen at 5 atmospheres are shown in Table 1 and compared with similar values obtained from rats pretreated with cysteamine 180 mg/kg 10 min before compression of the animal, and cysteamine plus CN<sup>-</sup> (2 mg/kg), the cyanide being given 2 min before cysteamine.

Table 1. SPLENIC  $pO_2$  (mm Hg  $\pm$  S.E.M.) IN RATS IN AIR AT 1 ATMOSPHERE OR IN OXYGEN AT 5 ATMOSPHERES ABSOLUTE

Treatment (No. trials)	Air	Maximum $pO_2$ at 5 atm.	$pO_2$ after 20 min at 5 atm.
Controls (85)	16 $\pm$ 2	344 $\pm$ 40	247 $\pm$ 37
Cysteamine (180 mg/kg) (39)	18 $\pm$ 2	251 $\pm$ 26 ( $P < 0.1$ )*	138 $\pm$ 26 ( $P < 0.05$ )*
Cysteamine (180 mg/kg) and cyanide (3 mg/kg) (23)	20 $\pm$ 2	246 $\pm$ 23 ( $P < 0.1$ )*	141 $\pm$ 37 ( $P < 0.1$ )*

\*  $P$  values compared with controls.

It can be seen that in rats breathing air cysteamine had no significant effects on splenic  $pO_2$ , as reported previously by van der Meer *et al.*<sup>1</sup>. Cysteamine plus  $CN^-$  also did not significantly affect normal splenic  $pO_2$ . At 5 atmospheres cysteamine did somewhat decrease splenic  $pO_2$  compared with control rats. This decrease was due in part to the increased number and severity of 'hump' responses after cysteamine: this type of response in spleen on compression of rats in oxygen has been described previously in detail<sup>2</sup>. The 'hump' response is characterized by an initial rise of tissue oxygen tension following compression, then a secondary fall in  $pO_2$ , although the external oxygen pressure is maintained constant. Hump responses were thought to be mediated through the adrenergic nervous system. Cysteamine has been shown to have an action in releasing catecholamines *per se*<sup>3</sup>, so it is possible that its potentiation of the 'hump' response is by this mechanism. In Fig. 1 an example of a marked 'hump' response to pressurization after cysteamine is shown.

Whatever the explanation for the form of the  $pO_2$  response in the spleen to pressurization, it is obvious that cysteamine has some action in lowering splenic  $pO_2$  during pressurization, but the splenic  $pO_2$  remains too high for the radioprotective effect of cysteamine to be explained as a result of hypoxia. The combined effect of cysteamine plus cyanide on rat splenic  $pO_2$  was almost exactly the same as cysteamine alone, both in air or 5 atmospheres of oxygen (Table 1). Thus cyanide plus high-pressure oxygen does not appear able to inhibit cysteamine radioprotection simply by altering tissue oxygen tensions.

It was thought that perhaps high-pressure oxygen reduced the number of active  $-SH$  groups through increased auto-oxidation, as occurs *in vitro*<sup>4</sup>. Thus total sulphhydryl and disulphide contents of the spleens of rats were measured, after exposure to 5 atmospheres of oxygen, and after combinations of high-pressure oxygen with cysteamine and cysteamine plus cyanide. The amperometric titration method with methylmercuric iodide was used as described by Jamieson, Ladner and van den Brenk<sup>11</sup> for lung tissue of rats, but in the present experiments 3 spleens were pooled for each determination.

It is seen from Table 2 that cysteamine raised the sulphhydryl level in the spleen ( $P < 0.001$ ), while the disulphide level remained constant. There is evidence that the spleen accumulated  $-SH$  groups, as the  $-SH$  content after cysteamine is higher than expected from equal distribution among tissues, and this result agrees well with the results of radioactive tracer experiment by Eldjarn and Nygaard<sup>12</sup>. Five atmospheres of oxygen had no effect on the endogenous  $-SH$  or  $-SS-$  content of the rat spleen. However, exposure to high-pressure oxygen did significantly reduce the increase of total splenic  $-SH$  groups produced by cysteamine (Group III v

Fig. 1. Splenic  $pO_2$ . Cysteamine (180 mg/kg) was injected intraperitoneally 5 min before pressurization. This figure illustrates the most pronounced version of the 'hump' response with a rapid increase in tissue oxygen tension followed by a severe secondary fall even though the chamber pressure is maintained at 5 atm.

Table 2. SULPHYDRYL ( $-SH$ ) AND DISULPHIDE ( $-SS-$ ) CONTENT OF RAT SPLEEN AFTER HIGH-PRESSURE OXYGEN (5 ATMOSPHERES) TREATMENT OF THE WHOLE RAT AND AFTER INTRAPERITONEAL CYSTEAMINE (180 mg/kg), AND CYSTEAMINE AND CYANIDE (3 mg/kg)

Group	Treatment (No. trials)	Total $-SH$ content $\mu$ moles/g wet tissue $\pm$ S.E.M.	Total $-SS-$ content $\mu$ moles/g wet tissue $\pm$ S.E.M.
I	Controls (9)	19.0 $\pm$ 0.6	3.4 $\pm$ 0.6
II	Oxygen, 5 atmospheres for 15 min (8)	18.5 $\pm$ 0.6	3.4 $\pm$ 0.8
III	Cysteamine, 30 min before killing (8)	22.0 $\pm$ 0.3	3.7 $\pm$ 0.5
IV	Oxygen, 5 atmospheres and cysteamine (10)	21.3 $\pm$ 0.4	3.5 $\pm$ 0.3
V	Oxygen, 5 atmospheres and cysteamine + $CN^-$ (8)	21.7 $\pm$ 0.4	4.0 $\pm$ 0.6

Group IV,  $P < 0.01$ , in Table 2), suggesting that oxygen administered under pressure *in vivo* produces faster oxidation of  $-SH$  groups from cysteamine. The administration of  $CN^-$  to cysteamine-treated rats failed to alter the changes in splenic  $-SH$  or  $-SS-$  content produced by cysteamine.

Thus the slight reduction of cysteamine radioprotection by high-pressure oxygen may possibly be due to a reduction by the latter of total  $-SH$  groups present during irradiation. However,  $CN^-$ , which appeared to act synergistically with high-pressure oxygen in partially inhibiting the radioprotective action of cysteamine, does not appear to exert this action by raising tissue oxygen tension in spleen, or by altering the  $-SH$  level of this tissue.

### Restoration of Irradiated Algae after a Period of Darkness

It has been found<sup>1</sup> that illumination applied between fractionated doses of X-rays slightly increases survival in the alga *Chlamydomonas*. Illumination during X-irradiation decreases survival in the same alga<sup>2</sup>. According to Godward<sup>3</sup>, visible light, if administered sufficiently soon after irradiation, has some restorative effect on X-irradiated algae.

In view of these findings, the effect of light and darkness on the survival of the unicellular desmid *Microsterias truncata* (Corda) Bréb. was investigated after  $\gamma$ -irradiation with a 350-c. cobalt-60 source. The algae were grown on mineral agar prepared according to Pringsheim<sup>4</sup>. For irradiation, young growing cultures were used. The cultures were illuminated with white fluorescent tubes for 15 h daily at 90  $\pm$  10 ft.-candles (two experiments were repeated at about 220 ft.-candles, but there was no perceptible difference in the results). Under these conditions the cells did not divide during the first part of the light period, that is, at the time when the irradiation was carried out. In order to follow the development of each cell after irradiation, irradiated cells were isolated with micropipettes and put on an agar surface in 10-cm Petri dishes (100–200 cells per dish).

A net consisting of 100 square fields drawn on a 'Cellophane' sheet was mounted outside on the bottom of the Petri dishes to facilitate counting.

Post-irradiation treatments consisted of: (a) incubation in 15 h light followed by 9 h darkness daily for 30 days; or (b) incubation in continuous darkness for various periods (from 1 to 4 days), after which the algae were exposed to the dark and light cycles as under (a).

Cells which grew into colonies with more than 10 cells in 30 days were designated as survivors.

The dose-response curve obtained after irradiation is a sigmoid, and in this respect corresponds to the curves obtained with other algae (*Oedogonium*<sup>1</sup>, *Chlamydomonas*<sup>2</sup>, *Stichococcus*<sup>3</sup>). This curve, plotted on a semi-logarithmic scale (Fig. 1), exhibits a marked shoulder up to doses of 4 kr., after which it descends approximately linearly. The straight portion of the curve (between 4 and 8 kr.) has a slope corresponding to a value of  $D_0 = 2$  kr. (dose required to reduce the surviving fraction  $S$  to 0.37  $S$ ). At doses higher than 8 kr. the curve is not reliable, as more cells should be used than permitted by our method. The extrapolation number<sup>4</sup> is approximately 5. Each point represents means of values of 300–600 cells which were examined in 3–5 experiments.

Post-irradiation incubation in darkness for 24–48 h had no significant effect on survival. An increase in the period of darkness following irradiation up to 3 and especially 4 days resulted in a visible increase in survival in the experiments with 5–11 kr. The survival of the irradiated algae increased after 3 days incubation in the dark following irradiation by a factor of 1.4–1.9, and after 4 days by a factor of 1.5–3.2 (for doses from 5 to 8 kr.). For lower doses the effect was less marked, as the surviving fraction was much higher. For this reason, with 4 days of darkness only doses from 5 to 9 kr. were used. The results are shown in Fig. 2.

Survival is not changed significantly and may even be improved if some light is admitted before the dark period (for example, if the irradiated algae are plated in light and afterwards put in darkness). It seems to be

Fig. 1. Survival of *Microcystis aeruginosa* after  $\gamma$ -irradiation. Vertical lines represent  $\pm 1$  standard deviation.

Fig. 2. Effect of light and darkness on the survival and cell divisions of irradiated algae *Microcystis aeruginosa*. Vertical columns represent the distribution of different colony-sizes of irradiated algae after 30 days incubation: L, incubation in light and dark cycles; 4D, 4 days incubation in the dark followed by 26 days in light and dark cycles; C, unirradiated control; DE, dead cells; F, cells that failed to divide; black, colonies of more than 10 cells; oblique lines, colonies with 2–9 cells; dotted, colonies with all cells dead after division except for one that survived. (The experiment with 8 kr. was carried out only once with 200 cells and, therefore, the discrepancy in the number of surviving cells does not seem to be of importance)

important that the algae should be placed in the dark before any cell duplication takes place.

No visible change in the cells could be microscopically detected before some development in the light takes place. During the period of darkness no growth or division occurs. It seems that the best results were obtained when the dark period exceeded the generation times of the control, which is  $77 \pm 4$  h.

Our results could not be compared with the findings of Jacobson on *Chlamydomonas*<sup>1</sup> as the duration of illumination period in his experiments was much shorter and was applied between fractionated doses. However, they agree with the fact shown by various authors (see, for example, refs. 8, 9) that different treatments which retard growth during the period immediately after irradiation increase survival.

### Fixation of Carbon-11 in the Cells of Proton-irradiated Blood

WHEN considering the possibility of marking cell populations with a short-lived, positron-emitting nuclide, carbon-11 ( $^{11}\text{C}$ ,  $T_{1/2} = 20.5$  min) appears to be suitable because, when produced through nuclear reactions in proton-irradiation of cells, it may be expected to react chemically with the intracellular material in the same way as it does with simpler organic systems<sup>1</sup>. Therefore it was decided to study to what extent  $^{11}\text{C}$  produced during irradiation of citrate blood is fixed in the cellular

fraction of the target. This report describes observations of the localization of  $^{14}\text{C}$  in human blood irradiated with 185-MeV protons. The radioactivity of whole blood, blood corpuscles and supernatant was followed during the course of a step-wise washing procedure after irradiation.

Three blood specimens, A, B and C, each containing 1.5 ml. of freshly drawn venous blood and 0.5 ml. 'Acodex' (for blood preservation), were irradiated individually with 5,000 (A), 5,000 (B) and 11,000 (C) rads in a broad parallel beam of 185-MeV protons from the synchrocyclotron at Uppsala<sup>1</sup>. After irradiation for five minutes the radioactivity was followed through intermittent measurement of the positron annihilation radiation under fixed geometry in a NaI (Tl) well scintillation crystal counter (efficiency for detection of one  $^{14}\text{C}$  disintegration  $\approx 0.6$ ). Results are given in Fig. 1 for 'whole blood' = specimen A and for the 'blood corpuscles' of specimen B collected after ten-fold washing in Ringer-phosphate at pH 7.4 (each volume of washing fluid = each volume of removed supernatant = 2 ml.). Fig. 2 shows the radioactivity in the 'blood corpuscles' and supernatant for specimen C at various intervals during the washing procedure (washing conditions as above). In the latter case the blood corpuscles, after eleven washings in Ringer-phosphate, were stored in 'Acodex' for 1 h before washing was started again.

It can be concluded from the curves shown in Fig. 1 that the radioactivities measured 50 min after irradiation or later in specimens of whole blood and of thoroughly washed blood corpuscles, respectively, are in both cases to a dominating extent due to disintegration of  $^{14}\text{C}$ . Both curves reveal an effective half-life of 20 min, which is, within the statistical uncertainty, identical with that of  $^{14}\text{C}$ . The ratio between the specific radioactivity of the washed erythrocytes and that of the whole blood is seen to be 0.47 and thus within the normal range of the venous haematocrit of man. Fig. 2 reveals that the  $^{14}\text{C}$  of the blood corpuscles at the employed dose of 11,000 rads has been strongly attached to the cells, since, after about ten centrifugations, neither subsequent washing nor incubation in 'Acodex' is able to remove any appreciable amount of radioactivity (less than 1 per cent for each of the two procedures). In no specimen were signs of haemolysis noted visually.

We conclude from the present findings that  $^{14}\text{C}$  may be fixed in the body of the blood cells simply through irradiation of blood with high-energy protons and this to an extent that seems to be of practical importance for

Fig. 1. Counting rate from whole blood (●) of specimen A and blood corpuscles (×) of specimen B. The blood samples were irradiated simultaneously and under identical conditions with 5 krad for 5 min.

Fig. 2. Counting rate from blood corpuscles and supernatant in specimen C during the procedure of washing following irradiation with 11 krad for 5 min. During time intervals 'ACD' the blood was preserved in 'Acodex'. 'Washing' indicates suspension in Ringer-phosphate with subsequent centrifugation and decantation. ×, Corpuscles; ●, supernatant; Δ, corpuscles with plasma in supernatant; ↓, washing.

labelling purposes. The site of fixation and the possible influence of varying conditions during and after irradiation, including the effect of systemic circulation, will be tested in further experiments.

## BIOLOGY

### Rhythmic Activity in Littoral Fish

TIDAL rhythms in invertebrates have been known for some time<sup>1-4</sup>. Recently, Williams<sup>5</sup> has described, by means of under-water observations, a tidal cycle of movement in *Olinocottus analis* (Girard) and *Girella nigricans* (Ayres). The tidally controlled movements of *Louresius tenuis*<sup>6-8</sup> and *Enchelyopus cimbrius* (L.)<sup>9</sup> are restricted entirely to breeding.

Preliminary investigations have been made on the activity patterns of several littoral fish using a modification of the apparatus designed by Harder and Hempel<sup>10</sup>. These have shown a very strongly marked tidal rhythm of activity in *Blennius pholis* (L.), peaks of activity occurring during the three to four hours around high water (Fig. 1).

This periodicity continues under conditions of constant light and temperature for at least five days, after which time the relative amplitude difference between active and inactive phases rapidly decreases. For the first 48 h the peak occurs approximately 1 h before high water, but

Fig. 1. Histogram illustrating the tidal rhythm in *Blennius pholis* (L.) over a period of 72 h. The vertical arrows represent the predicted time of high water.

gradually the period length tends to increase, so that the highest level of activity occurs nearer the predicted time of high water.

Table 1 gives the results of nine experiments performed in conditions of constant light (Nos. 5-10) and darkness (Nos. 16-19)

Table 1

Experiment No.	Mean period (h)	Phase difference Start (h)	Phase difference Finish (h)	Duration of experiments (h)
5	12.5	-1.1	-0.7	30.5
6	12.5	-2.3	0.0	44
8	12.4	-1.5	-0.7	74
9	12.6	-0.2	0.0	72
10	12.8	-0.7	+3.0	115
16	12.4	+0.2	+0.7	64
17	12.4	-1.6	-1.1	64
18	12.3	-0.4	-1.1	88
19	12.9	-1.5	+1.8	75

The mean periods for the experiments in darkness (12.56 h) and in light (12.5 h) are only slightly greater than the period of the lunar cycle.

There is no diurnal component evident in the rhythm, as in *Carcinus maenas* (L.)<sup>4</sup>, although in conditions of constant illumination the fish have a mean level of activity which is greater than that in constant darkness.

Records obtained in alternating periods of light and darkness showed that the fish respond directly to light by increased activity. This results in a different pattern of activity in light and in darkness. Peak activity in the light is sustained at a higher level for a longer period than in darkness.

Other fish studied were *Acanthocottus bubalis* (Euphrasen) and *Oiliata mustela* (L.). *A. bubalis* showed a short-lived (24 h) tidal cycle after which activity remained at a constant level. *O. mustela* when studied in the same apparatus appears to be arrhythmic in its activity.

The functional significance of the tidal rhythm in *Blennius pholis* is as yet unknown, although there are indications that it is connected with feeding migrations outside the tide pools in which it rests at low tide.

## Micropores in the Cross-wall of *Geotrichum candidum*

Two types of septal pores have so far been conclusively demonstrated in fungi, the simple pore of the ascomycete type<sup>1,2</sup> and the more complicated pore found in the basidiomycetes<sup>3,4</sup>.

It was therefore most interesting to read of pores in the imperfect fungus *Geotrichum candidum* as shown by a shadowing technique. These did not correspond to either of the foregoing types of pore<sup>5</sup>. Hashimoto *et al.*<sup>6</sup> stated that they were not as yet able to demonstrate these pores by the conventional method of fixation, embedding and ultrathin sectioning, but we have now confirmed their results by this method. A 24-hour-old culture of *Geotrichum candidum* was fixed in 2 per cent KMnO<sub>4</sub> for 30 min, and embedded in epoxy resin<sup>7</sup>. After being cut, the sections were stained with lead hydroxide to increase contrast<sup>8</sup>. The material was viewed with a Siemens Elmiskop electron microscope operating at 80 kV.

Fig. 1 shows a cross-wall in section with two pores in median section and two other pores. These pores widen towards the cell interior, having a minimum diameter of approximately 300 Å and a maximum opening into the cell of about 600 Å. The cross-wall is composed of a thin electron-transparent central layer, between two thicker, more electron-dense, layers. The ectoplasm cannot be resolved clearly. The dense nature of the micropore indicates a dense cytoplasmic connexion between the cells. Fig. 2 shows that the micropores often occur in groups.

Fig. 1. Electron micrograph of part of the cross-wall of *Geotrichum candidum* showing four micropore connections between adjacent cells. (x 64,000)

Fig. 2. Electron micrograph of the same cross-wall in the next serial section. Some of the pores appearing in Fig. 1 are already out of the section in this figure. (x 64,000)

The term 'septal pore' proposed by Hashimoto *et al.*<sup>4</sup> is not accepted in this case since this term has been applied to the much larger pores of the ascomycete and basidiomycete type. The term 'septal micropore' is proposed for the pore type seen in *Geotrichum candidum*.

Hashimoto *et al.*<sup>4</sup> have likened the small pores observed to the pits in higher plant cell walls. This interpretation should not be accepted because the pit of a higher plant is an unthickened part of a secondary wall, and plasmodesmata in higher plants are the cytoplasmic connexions between adjacent cells. In the ascomycete and basidiomycete type of pore the intercellular connexion is not considered a plasmodesmata by virtue of the way in which they are formed<sup>5</sup>. The 'septal micropores' shown here, however, are of the nature of plasmodesmata.

We thank Dr. H. J. Swart for supplying the culture of the fungus studied.

### Retarded Embryo Sac Development in Irradiated Clones of *Malus sylvestris* Hort. cv. 'Golden Delicious'

SEVEN 'Golden Delicious' apple clones propagated from buds irradiated at 5,000 r. in a cobalt-60 source were selected for high, intermediate, and low pollen abortion. Pollen abortion was 4.9 per cent in a typical check clone, and varied in the irradiated clones from 10.4 per cent to 84.8 per cent. Blossoms collected at anthesis were sectioned serially at 10 $\mu$  thickness and stained with Heidenhain's iron alum haematoxylin for embryo sac examinations.

Increased pollen abortion was associated with decreased proportions of differentiated (migrating polar nuclei) 8-nucleate embryo sacs. The check clone had 52.2 per cent of its embryo sacs at this stage; the treated clones with 52.9 per cent or less pollen abortion (group 1) had 36.2 per cent at this stage; the intermediate clone (group 2) with 68.0 per cent aborted pollen had 24.3 per cent of its embryo sacs at this stage; and the clones with 70.6 per cent or more pollen abortion (group 3) contained only 9.6 per cent differentiated 8-nucleate embryo sacs. There was a highly significant negative rank correlation ( $r_s = -0.952$ ) between the percentage pollen abortion and the percentage of differentiated 8-nucleate embryo sacs.

As pollen abortion increased, relatively more embryo sacs proceeded an 8-nucleate stage. The check clone had

14.6 per cent of its embryo sacs at the 2- or 4-nucleate stage; group 1 had 20.5 per cent; group 2 had 31.4 per cent; and group 3 had 36.4 per cent of its embryo sacs at this stage. Megaspore mother cells and megaspores were found only in clones with 70.6 per cent or more pollen abortion, except that one megaspore was found in clone 23-26. There was a highly significant positive correlation ( $r_s = 0.952$ ) between pollen abortion and the total percentage of megaspore mother cells, megaspores, and 2- or 4-nucleate embryo sacs. The average number of ovules per pistil was fairly uniform from clone to clone and showed no clear relationship to pollen abortion (Table 1). Irradiation did not materially reduce the proportion of normally developing embryo sacs, or influence the relatively infrequent occurrence of supernumerary or degenerate embryo sacs.

The results of investigations with this cultivar suggest that irradiation resulted in retardation of female gametophyte development. Furthermore, there was a close association between pollen abortion and retarded embryo sac development.

We thank K. Lapins of the Canada Department of Agriculture, Research Station, Summerland, British Columbia, for his advice and for making available his irradiated clones for blossom collections. This work was supported by the National Research Council of Canada.

### Effect of Light Intensity on the Metabolic Pathways in Photosynthesis

TRACER experiments indicate that different substances (carbohydrates, proteins, lipids) are synthesized in plants, even after a short exposure to <sup>14</sup>CO<sub>2</sub> (ref. 1). Therefore, although photosynthesis starts with a single primary reaction, a number of photosynthetic pathways lead to various photosynthetic products. We have investigated the effect of light intensity on these alternative pathways.

The investigations were made in a light thermostat<sup>2</sup>, using *Phaseolus vulgaris* L. (var. 'Sugar Bean') plants grown in sand culture. Low light intensities were applied because the effect of the light factor (near the minimum) is in this way more pronounced. Carbohydrates<sup>3</sup> and nitrogen<sup>4</sup> were estimated from three-week-old plants.

It was found that an increasing light intensity proportionally raises the relative carbohydrate contents of the plants (Fig. 1). This rise seemed to be steady in the starch and soluble carbohydrate fractions up to 2,000 lux; however, at 4,000 lux there was a dramatic increase in the starch fraction of the leaf and in the soluble carbohydrate fraction of the stem.

Table 1. CONDITION OF EMBRYO SACS IN CHECK AND IRRADIATED 'GOLDEN DELICIOUS' APPLE CLONES ARRANGED IN ORDER OF INCREASING POLLEN ABORTION

\* 8-nucleate sacs were classified as differentiated when the polar nuclei had begun to migrate.

The relative nitrogen contents of the plants decreased in proportion to increasing light intensities (Fig. 1). The decrease appeared in the soluble nitrogen fraction. The level of protein nitrogen remained constant at different light intensities.

The results indicate that at low light intensities photosynthesis results in a higher proportion of nitrogen compounds, while at higher light intensities the formation of carbohydrates is dominant. Referring to Katchman's investigations<sup>4</sup>, we interpret our findings to show that the metabolic pathways of the production of photosynthetic carbohydrate and nitrogen compounds are interlinked through pyruvic acid. In consequence of its lower energy content the low light intensities allow photosynthesis to follow pathways utilizing less energy. During photosynthesis a considerable amount of energy is utilized for the fixation of  $\text{CO}_2$  and for the reduction of phosphoglyceric acid. This second energy-requiring step may be missed when phosphoglyceric acid is transformed, without reduction, into alanine through pyruvic acid (Fig. 2). In this case amino-acids are formed rather than carbohydrates. The former way continues to build up proteins; this process, however, requires energy because of the synthesis of peptide bonds and because the activation of amino-acids requires ATP<sup>5,6</sup>. The lower level of soluble nitrogen and unchanged level of protein nitrogen, evoked by increasing light intensity, are in line with the foregoing statement.

During the carbohydrate-producing pathway of photosynthesis phosphoglyceric acid is reduced to the triose-phosphate level (Fig. 2). It is reasonable to suppose that this reduction may prevail over the other pathway of photosynthesis only at high light intensities<sup>8</sup>. In our experiments it was observed at 4,000 lux. This light intensity is nearest to those under which photosynthesis takes place under natural conditions, when primarily carbohydrates are produced, accumulated in the leaf, and transported to other parts of the plant. The sudden increase in the starch content of the leaf and in the soluble carbohydrates in the stem, measured at 4,000 lux, confirms these statements.

The energy necessary for these energy-consuming processes is available to the plant as ATP and NADPH. These energy carriers are produced during photophos-

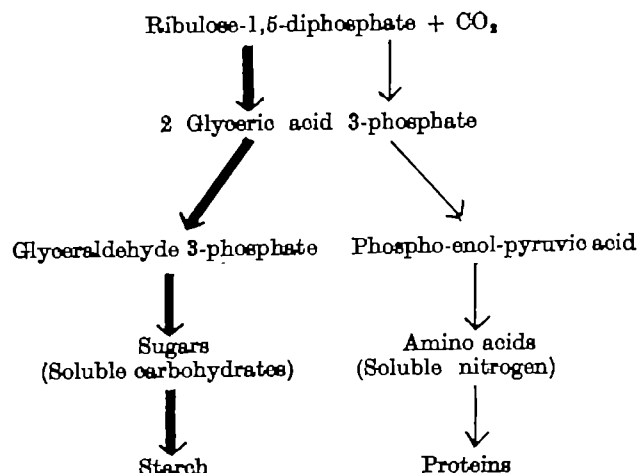

Fig. 2. Alternative metabolic pathways in photosynthesis. At low light intensities reactions marked — are more active, but at high light intensities reactions marked - - - are dominant

phorylation. Studying the dependence of photophosphorylation upon the light intensity, several authors<sup>9,11</sup> have established that it shows a lag phase below 1,000 lux and then a linear relationship up to 10,000–20,000 lux. These statements are in line with our findings about the prevalence of energy requiring carbohydrate synthesis above 2,000 lux.

## Chromatic Adaptation in Benthic Marine Algae

In rocky coastal waters of the North Atlantic the well-defined zonation with depth of green, brown and red algae is still frequently ascribed to changes in the quantity and quality of light reaching the different habitats. There is little direct evidence that this 'chromatic adaptation' in fact occurs, and reports (for example ref. 1) from other parts of the world indicate that this zonation may not be universal.

To determine whether light is a primary factor in controlling the standing population of attached marine algae, a site is needed where as few other factors as possible change with depth. It seemed desirable to select a locality where the currents and the amplitude of the tide are small and the water is clear, and to investigate a site with a vertical rock face. These requirements are met on the south coast of Malta where there are rock faces falling sheer to sixty metres below sea level. During the summer of 1963 an expedition was organized to study the vertical distribution of the algal species. Aqua-lung diving equipment was used to sample the algal population, and a fixed vertical line, suitably marked, indicated the depth.

To ascertain what should be the area of a sample, samples of varying size were collected and the number of species in each was recorded. When this number was plotted against area it was found that 400 cm<sup>2</sup> approximated to the minimal area of the community. The method of collection was to remove the algae by means of a chisel, and collect them in a hessian bag attached to the frame of the sampling quadrat. Four collections were made at each selected depth and were later sorted into species, dried at 80° C and weighed. In addition, heats of combustion of the dried samples were determined using a Galenkamp 'O.B.370' bomb calorimeter. Light measurements were made with a Weston 'Universal' exposure meter (S461-4): a comparison of the data with those of Jerlov<sup>2</sup> indicated that the transparency of the water was between his types 1 and 2.

Of 40 algal species present, the following formed more than 95 per cent by weight of the standing population:

Chlorophyceae—*Udotea petiolata* (Trev.) Boerg., *Halimeda tuna* (Ellis and Sol.) Lam. Phaeophyceae—*Diclyotoma dichotoma* (Huds.) Lam., *Padina pavonia* (L.) Gail., *Cystoseira* spp., *Sargassum vulgare* Ag. Rhodophyceae—*Polysiphonia subulifera* (Ag.) Harv.

From Fig. 1 it is at once apparent that there is no clear-cut zonation of green, brown and red algae with depth. Near the surface the stand consists very largely of Phaeophyceae, whereas at 45–60 m the proportion is very small. The proportion of Chlorophyceae becomes significant at 15 m, and the trend is for the proportion to increase with

depth. Although a few Rhodophyceae were observed at depths of 15 and 60 m, appreciable amounts were confined to 30–45 m. In Fig. 2 the total weight collected per quadrat is plotted against depth, together with the changes in light intensity and temperature.

Two facts emerge quite clearly: first, that the pigmentation of the dominant algae seems to be unrelated to their distribution with depth; secondly, that the standing population as measured by dry weight (and by calorific value) bears no simple relationship to light quantity, temperature or depth, down to 60 m.

Although the work of Haxo and Blinks<sup>3</sup> on the enhancement of photosynthesis in red algae at certain light wave-lengths has been taken as evidence for chromatic adaptation, the link between photosynthetic efficiency and standing population is tenuous. The standing population represents a balance between complexes of synthesis and attrition, and Blinks<sup>4</sup> quotes data which show that the net yield of a variety of algal species bears little relation to the mass of the standing population. Perhaps more important is the inability of some species to establish themselves in a particular habitat<sup>5,6</sup>. It is possible that a more efficient growth in the sporeling stage accounts for the increase in the number of red algal species with depth<sup>7</sup> despite the dominance of the biomass by the other algal species, such as the green algae *Halimeda* and *Udotea*, which seem to propagate mainly by vegetative means.

It is concluded that the theory of chromatic adaptation is inapplicable to the results of the present investigation. Field observations on the causation of zonation in the marine environment can only be adequately interpreted in the light of long-term studies on establishment, environment, competition and productivity.

We thank the Royal Society for a travel grant, and the Linnean Society, Sir Maurice Bowra, members of the Royal University of Malta, and many others for invaluable help and advice. We also thank Prof. G. E. Blackburn for his advice.

## ENTOMOLOGY

### Photoperiodic Control of the Maintenance and Termination of Larval Diapause in *Chironomus tentans*

DURING recent years, dipterous larvae possessing giant polytene chromosomes have provided important new insight into developmental physiology at the sub-cellular level. This is in large measure attributable to the phenomenon of chromosomal 'puffing', which has afforded the opportunity for visualizing the changing pattern of genetic activity within individual tissues during the course of development<sup>1</sup>. Clever<sup>2</sup> has reported significant alterations in the puffing pattern of salivary gland chromosomes from a laboratory population of *Chironomus tentans* which experienced a state of spontaneously arrested development under conditions seemingly favourable for continued growth and metamorphosis. Although not previously described for this organism, the developmental arrest resembles the diapause which typifies the life-histories of many insect species. Diapause is commonly induced or terminated by extrinsic environmental factors, particularly temperature and photoperiod, which exert their effect by

influencing the activity of the endocrine system which regulates insect growth and metamorphosis<sup>6</sup>. In view of the paucity of information on these matters in the case of *C. tentans*, coupled with the general utility of diapausing insects and the special cytological attractions of this species for investigations of biochemical mechanisms underlying growth and differentiation, we have examined the natural occurrence of a larval diapause and its photoperiodic control under laboratory conditions.

The insects used in the work recorded here were collected among mud and debris from the bottom of a shallow woodland pond in Ann Arbor, Michigan. They were transferred to the laboratory and housed at 18°–22° C in covered dishes of pond water contained within closed incubator cabinets. Small pieces of filter paper were added to aid the larvae in constructing their dwelling-tubes; and food was provided regularly in the form of a powder prepared from dried nettle leaves<sup>7</sup>. Illumination was supplied in each cabinet by a 20-W 'cool-white' fluorescent lamp located at a distance of 35–45 cm, and set to provide either 8 h of light alternating with 16 h of darkness (henceforth termed short-day conditions), or 16 h of light alternating with 8 h of darkness (long-day conditions).

Two groups of larvae were examined. The first group included 50 larvae of apparently mature size collected on October 14. These were maintained under short-day conditions. During the next 40 days none exhibited any substantial growth or showed any sign of commencing the sequence of developmental changes which commences with formation of the prepupa and which, at 20° C, culminates about one week later with the emergence of the fully formed adult insect. A total of 12 larvae were then transferred to long-day conditions. In the next 9 days, 3 prepupae and 2 pupae had already formed from among the insects exposed to long-day conditions, while none of those under short-day conditions initiated development. A total of 9 larvae died under short-day conditions, while 2 of those under long-day conditions died, all without initiating development. The experiment was terminated at this point to provide material for other investigations.

The second group of larvae also consisted of 50 individuals of mature size, collected on December 16 from beneath the pond's ice cover of 10 cm. Under short-day conditions during the next 36 days, the majority failed to exhibit any developmental progress and remained as larvae. A total of 20 larvae were then transferred to long-day conditions. Of these, 13 initiated development shortly thereafter, yielding 6 prepupae, 5 pupae, and 2 adults in a period of 2 weeks; while 2 larvae died and 5 remained alive without initiating development. This prompt resumption of development in the majority of individuals transferred to long-day conditions contrasts sharply with the behaviour of the larvae maintained under short-day conditions, among which only 5 individuals sporadically initiated development from the time of their collection until termination of the experiment. Under short-day conditions, 17 larvae died during the 7 weeks' duration of the experiment.

On the basis of the foregoing findings, it is likely that the arrest of development in *C. tentans* is not simply a quiescence enforced directly by temperatures too low to permit development, since the majority of larvae did not develop when maintained at temperatures suitable for rapid growth and metamorphosis. In terms of the criteria summarized by Lees<sup>8</sup>, a genuine diapause appears to be involved. Short-day conditions favour the maintenance of diapause, while its termination is favoured by exposure of larvae to long-day conditions. To the extent that our population of *C. tentans* is representative, the larval diapause reported here resembles that of the pitcher plant midge, *Metricnemus knabi*, and the other Diptera summarized by Paris and Jenner<sup>4</sup>, also the larval diapause of the European corn borer, *Ostrinia nubilalis*<sup>9</sup>, as well as the pupal diapause of the Chinese oak silkworm, *Antheraea pernyi*<sup>10</sup> to mention but a few examples.

The fact that larvae of *C. tentans* and related species do not continue to develop under natural conditions in autumn and winter has previously been reported<sup>7</sup>; but little attention has been directed to the underlying physiological basis. Based on his findings during the mass rearing of *C. tentans* 30 years ago, Sadler<sup>7</sup> suggested that the arrest of development was a direct effect of low temperature, because metamorphosis was observed when the temperature was maintained above the prevailing outdoor level. However, these conclusions now seem open to re-examination since the effect of photoperiod was not considered at the time. Indeed, Prof. Sadler has informed us in a personal communication that his cultures were in fact routinely exposed to daylight supplemented by at least several hours of artificial light. The net result appears to have been illumination almost equivalent to the long-day conditions used in the work recorded here. While the critical day-length has not yet been determined, our findings appear to be reconcilable with those of Sadler as soon as photoperiod is taken into account.

Although the induction of diapause by appropriate photoperiodic stimuli is known to occur in many insects<sup>8,9</sup>, reports on the photoperiodic control of its maintenance and termination have been relatively scarce<sup>1</sup>. Together with those of the recent investigations already cited<sup>4–6</sup>, the findings reported here provide increasing evidence that photoperiod is of widespread significance in regulating the maintenance and termination of diapause as well as its induction. The prompt response of *C. tentans* in initiating development when exposed to long-day conditions, coupled with its rather stable diapause when exposed to a short day-length, suggests that this species may provide favourable material for examining the physiological processes that intervene between imposition of a particular photoperiod and its developmental consequences. Of particular interest in this connexion is the endocrine basis of the diapause, the means whereby the photoperiodic stimulus is integrated in a manner capable of controlling the endocrine system, and the cytological manifestations in the endocrine and target organs. Experiments are now in progress to elucidate these and other matters which remain unanswered by present results. Meanwhile, in view of the characteristic differences in the pattern of chromosomal puffing in tissues of non-developing as compared with developing larvae of *C. tentans*<sup>8</sup>, the results of this work suggest that control of photoperiod is desirable during investigations of chromosomal function in this insect, and on the action of the insect's endocrine system thereupon.

We thank Dr. H. K. Townes for confirming the identification of *C. tentans*, and Prof. W. O. Sadler for helpful information. This work was supported by research grant GM-06101 from the U.S. Public Health Service, and by a fellowship to one of us (W. E.) from the Thyssen-Stiftung.

## MICROBIOLOGY

Non-conservation of  $H^3$ -Thymidine Label in the DNA of Growing Yeast Cells

WHILE investigating the kinetics of transfer of DNA from the parent to the progeny in yeast cells with the help of tritium autoradiography, we found that there occurs considerable degradation of the labelled DNA at the onset of the stationary phase of growth. The relevant experiments are described and the underlying possibilities are discussed.

A small inoculum of *S. cerevisiae* was grown overnight in 1.5 ml. of a nutrient medium containing 1 per cent peptone and 4 per cent maltose in distilled water (pH 5.0) supplemented with 3.3  $\mu$ Ci/ml. of  $H^3$ -thymidine (specific activity: 360 mCi/mM, Schwarz BioResearch, Inc.). The cells were then centrifuged down, washed thoroughly and resuspended in 10 ml. of 'cold' medium without  $H^3$ -thymidine. At specified intervals, haemocytometer counts were taken and smears were prepared on gelatinized glass slides. The cells were fixed for 3 h in the following fixative: 1 per cent chromic acid, 25 ml.; 2 per cent acetic acid, 5 ml.; 2 per cent mercuric chloride to make 100 ml. Fixed cells were then treated with cold 2 per cent perchloric acid (PCA) to remove all unincorporated nucleotides.

After thorough washing and dehydration, the slides were covered with autoradiographic stripping film (Kodak 'AR 10') in the usual manner, air-dried and exposed in an atmosphere of dry  $CO_2$  at 4° C for 16 days. Exposed slides were then developed in Kodak developer 'D19b' for 10 min and fixed in Kodak acid fixer—all at 20° C. After washing, the slides were air-dried and briefly stained with toluidine blue (0.05 per cent w/v in distilled water).

Autoradiographic grain counts were done at a magnification of 1,250 using an oil-immersion objective. A representative autoradiograph is shown in Fig. 1. The background varied between 0.1 and 0.8 grains/25 $\mu^2$ , which is the average area of a yeast cell. To check that the grains observed were due to  $H^3$ -thymidine incorporated into the DNA, a few slides containing labelled cells were treated, prior to autoradiography, with 100  $\gamma$ /ml. of crystalline DNase I (Worthington Biochemicals Corporation) in 0.005 M  $Mg^{++}$ , pH 6.8, at 37° C; 15- and 30-min treatments removed 50 per cent and 70 per cent of the grains, respectively.

The total number of grains that would have been produced by the labelled cells contained in 1 ml. of culture (column 4, Table 1) is proportional to the amount of labelled DNA/ml. and should therefore remain constant unless dispersion and/or degradation occurs during the growth of the cells. It will be seen from Fig. 2 that between 2.5 h and 4 h of growth, that is, while the percentage of budding cells in the population is constant and high at ~80 per cent, the amount of the labelled DNA/ml. of culture remains constant. During this period, the cell number also increases exponentially (column 2, Table 1). Thus during the exponential phase of growth there is no degradation of DNA, which is in accord with the generally accepted view that nuclear DNA is metabolically stable.

However, after 5 h, when the rate of formation of buds begins to slow down, that is, when the cells enter the early stationary phase, the total number of grains or the amount of labelled DNA/ml. falls sharply to about half

Fig. 1. Autoradiograph of yeast cells showing grains due to  $H^3$ -thymidine incorporated into DNA. Fully labelled cells were allowed to grow in 'cold' medium for 4 h before fixation. ( $\times 1,200$ )

Fig. 2. Plot of the total number of grains that would have been produced by the  $H^3$ -thymidine labelled yeast cells per ml. of culture (hatched bars) at different periods of growth in 'cold' medium. The solid curve shows the fraction of viable buds in the cell population.

its value in the exponential phase. The sharpness of the fall in the amount of the label, as well as its coincidence with the onset of the stationary phase, suggests that it is not due to some dilution process arising out of asymmetric distribution of the labelled DNA during cell growth and that an actual release of incorporated  $H^3$ -thymidine must have taken place.

Schmidt *et al.*<sup>1</sup> have shown that starving yeast cells release nucleotides in a cold TCA-soluble fraction, thereby showing the instability of nucleic acid under these conditions. Halvorsen<sup>2,3</sup> claimed that intracellular turnover of proteins and nucleic acids is characteristic of resting yeast cells, while it is almost absent during the period of active growth. Using  $^{14}C$ -adenine as nucleic acid precursor, he also showed<sup>2</sup> that when the cells are incubated under conditions favouring protein degradation, the radioactive label is released into the TCA-soluble fraction and to a lesser extent into the medium. However, chromatographic analyses by other workers<sup>4,5</sup> of materials released into the suspending medium did not reveal the presence of DNA or its degradation products such as thymidylic acid, deoxyribose, etc.

In the light of the above findings, it is plausible to assume from the present data that DNA begins to be degraded at the onset of the stationary phase, then is released into the cytoplasm and finally removed by the treatment with PCA prior to autoradiography. In this connexion it will be interesting to ascertain the genesis of a small single-stranded polydeoxyribonucleotide which has recently been found associated with the crystalline L(+) lactic dehydrogenase (YLDH) cytochrome  $b_5$  of dry baker's yeast<sup>6</sup>.

Another possibility is that there is no actual degradation of DNA during any stage of growth, but it is rendered more susceptible to cold PCA treatment as the cells enter the stationary phase due to some unknown alteration in the structure of DNA or of the DNA-protein complex.

We thank Prof. N. N. Das Gupta for his advice. One of us (S. K. S.) is supported by a senior research fellow-

### Plaque-formation on the Chorioallantoic Membrane, by Isologous Spleen Cells, under the Influence of Homologous Bursa of Fabricius Cells

THE thymus and the bursa of Fabricius are both essential for the development of immunological competence in birds. The bursa of Fabricius seems to be responsible for the development of the cells producing serum antibodies<sup>1</sup> and delayed hypersensitivity reactions<sup>2</sup>, whereas the thymus is more particularly involved in homograft reactions<sup>3,4</sup>. The fact that the thymus shows evidence of at least partial activity when implanted in a 'Millipore' chamber impermeable to cells<sup>5</sup> suggests that its influence is humoral.

If the bursa is instrumental in inducing cells to become immunologically competent it could extend this function either (a) by creating conditions which enable inactive cells to start making antibody, according to their predetermined capacity, or (b) by inducing responsive cells to produce antibody in answer to any antigenic stimulus.

To test this, we used the phenomenon of production of plaques (nodules) on the chorioallantoic membrane (CAM) of developing chick embryo by inoculation of a suspension of blood or spleen cells<sup>6,7</sup>. When the recipient embryo and the donor of the blood or spleen cells belong to different strains, the intensity of the plaque reaction is determined by the genetic differences between the strains<sup>8</sup>.

We found that with highly inbred strains which are comparable with pure lines of mice, very few plaques appear, whereas with crossbred strains the embryos show plaques in great numbers. Numerous plaques appeared at 95-98 per cent of the embryos when cells of a foreign strain such as Australorp - (A), White-Rock or New-Hampshire were inoculated on the CAM of Leghorn Schatz Israel (LSI) embryos. In contrast to that when LSI embryos were inoculated with cells of an adult hen of the same inbred strain, only 2 per cent of the embryos reacted, with the appearance of occasional plaques<sup>9,10</sup>.

The experiments that we report here consist of the inoculation of a combination of isologous spleen cells of adult (8-8 month) hens ( $10^4$  cells per inoculation) with the same quantity of homologous bursa cells. This combination caused the appearance of plaques. Bursa and spleen cells alone were ineffective. The ability of the bursa cells to induce plaque formation was dependent on the age of the bursa donor.

Inoculations on the CAM were performed on the 9th day of incubation and the results were examined after another 5 days. Of 112 LSI embryos inoculated with bursa cells ( $2 \times 10^4$  cells per inoculation) of A-chicken (5-16 weeks) none showed the appearance of plaques. Only 5 out of 103 LSI embryos inoculated with LSI spleen cells ( $2 \times 10^4$  cells per inoculation) showed plaques. In 66-84.6 per cent of the embryos inoculated with the combination of spleen and bursa cells of this age-group, plaques appeared in significantly great numbers in contrast to inoculations with spleen and bursa cells alone. When the bursa donor

Fig. 1. Effect of inoculation with bursa cells and spleen cells. Bursa cells alone caused no formation of plaques. —, Spleen cells alone; —, bursa cells + spleen cells.

was younger or older, the number of positive results diminished, as seen in Table 1 and Fig. 1. Maximum reactivity of the bursa cells was observed at the age of 11-13 weeks.

Table 1. APPEARANCE OF PLAQUES ON THE CAM OF LSI EMBRYOS INOCULATED ON THE 9TH DAY, 5 DAYS AFTER INOCULATION WITH SPLEEN CELLS OF AN ADULT LSI, AND BURSA CELLS OF STRAIN A

Age of bursa donor (weeks)	A bursa cells alone	LSI spleen cells alone	A bursa cells + LSI spleen cells

Number of cells inoculated was  $2 \times 10^4$  per inoculation; numerator = the number of embryos with plaques; denominator = total number of embryos inoculated; % = percentage of positive results obtained.

These experiments confirm the fact that isologous spleen cells are unable to react in the CAM of their own strain. The small number of plaques in a low percentage of embryos could be explained through some residual antigenic heterogeneity of the 'pure' strain, possibly because of sex differences, although we tried to use only hens and no cocks as donors.

The results of the experiments show that isogenic cells cannot react against their own antigens present in the embryo; in the terminology of Burnet<sup>11</sup>, these spleen cells are tolerant to isologous cells, but are induced to recognize the same antigen as foreign when under the influence of homologous (allogenic) bursa cells.

**Addendum.** Attempts to reproduce the results with other strain combinations were not fully successful. The strain Leghorn Schatz has now lost its purity through cross-breeding.

We thank Mr. J. Shlomo and Mrs. N. Raz for their help. This work was supported by a grant from the National Council for Research and Development, Israel.

## VETERINARY SCIENCE

## Tolerance and Excretion of Mimosine in the Fowl

Hegarty, Schinokel and Court<sup>1</sup> have reported the use of isolated mimosine ( $\beta$ -[N-(3-hydroxypyridone-4)]- $\alpha$ -aminopropionic acid) in metabolism investigations with sheep. They reported that the major metabolite 3,4-dihydroxypyridine (DHP) was present in the urine, and that degradation of mimosine to DHP occurred in the rumen, the animal being unable to detoxicate the material after absorption. No comparable work on the fowl has been located in the literature.

As a continuation of toxicity investigations of *Leucaena leucocephala* in the fowl, an experiment was designed to determine the route of excretion and possible degradation of mimosine. Since urine and faeces are excreted through a common opening (cloaca) in the fowl, it was necessary to effect a separation of the excreta by surgical means. This was accomplished through a modification of the method of Ariyoshi and Morimoto<sup>2</sup> on a 6-month-old cross-bred cockerel.

Mimosine was isolated from the seed of *L. leucocephala* and purified according to the method of Hegarty, Schinokel and Court<sup>1</sup>. The sample of mimosine used was analysed for purity and its breakdown product, according to the method of Hegarty, Court and Thorne<sup>3</sup>. The purity was found to be 98 per cent mimosine. DHP was not present in the sample.

After the bird had sufficiently recovered from the operation, 1 g of mimosine was administered *per os* in gelatine capsules, and the urine and faeces were collected in polythene bags supported by a harness around the bird's neck. Urine and faecal samples were collected hourly over a 24-h period and analysed for mimosine and DHP. No mimosine or DHP was found in any of the faecal samples. This is contrary to the results obtained by Yoshida<sup>4</sup>, who reported that 32-42 per cent of ingested mimosine was excreted in the faeces of rats fed 0.89 per cent of mimosine in the diet for 3 weeks.

Of the mimosine excreted in the urine, approximately 85 per cent appeared in the first 5 h following administration and thereafter only minor amounts or traces appeared. No trace of any DHP was found in any of the urine samples. Of the 1 g of mimosine administered, a total of 42 mg, or 4.2 per cent, was accounted for in the urine over the entire 24-h collection period. Since there was never more than 0.2 mg excreted during any 1 h after the first 10 h of collection, it would appear that most of the ingested mimosine was rapidly metabolized by the fowl.

It is difficult to compare these results with those of Yoshida<sup>4</sup>, since her rats received mimosine as a part of their diet for 2 or 3 weeks. However, the 1 g of mimosine that the fowl received would have been approximately equal to the amount that it would have consumed in a 24-h period if the mimosine had been added to the diet at the rate of 0.89 per cent. On this basis it would appear that the fowl is better able to detoxify and metabolize mimosine than is the rat: 96 per cent as compared with 15-28 per cent<sup>4</sup>.

In order further to test the apparent tolerance of the fowl for mimosine, a 2-month-old White Leghorn cockerel was injected intraperitoneally with a sterile 1.5 per cent solution of mimosine, prepared as a sodium salt<sup>5</sup>. The bird was injected with 5.8 ml. of mimosine solution a day for a total of 9 days, then with 11.6 ml. a day for the next 6 days.

The bird suffered no apparent untoward ill-effects from the mimosine injections. It remained bright throughout the period, and continued to thrive and to gain weight. There was no apparent increase in the number of feathers shed, nor was there shedding of the toenails.

The cockerel was able to withstand the administration of almost 2 g of mimosine in 15 days, that is, at the rate

of 2.7 g/kg body-weight. Hegarty, Schinokel and Court<sup>1</sup> administered a similar solution to sheep for 8 days, at the rate of 0.68 g/kg, which resulted in shedding of the fleece and hooves, and finally death. It can therefore be assumed that the bird is far more tolerant to injections of mimosine than the sheep.

## GENETICS

## Autoradiographic Studies of the Chromosomes in Chronic Granulocytic Leukaemia

THE work to be described here was carried out with the particular aim of investigating the labelling pattern of the  $Ph^1$  chromosome in chronic granulocytic leukaemia<sup>1,2</sup>. Blood and bone marrow samples were obtained from one male patient (A. C.) and blood from two female patients (J. S. and V. C.).

**Bone marrow.** Preliminary experiments with bone marrow indicated that direct *in vitro* labelling with tritiated thymidine was not possible. 6 h after aspiration, which was the minimum time necessary to obtain labelled mitoses, the mitotic index was very low. Bone marrow cultures were therefore set up and collected at 24, 48 and 72 h respectively. Tritiated thymidine (specific activity 14.8 c./mmole) was added to a final concentration of 1  $\mu$ Ci/10 ml. of medium at 6 h and colcemid, 0.04 ml./10 ml. of medium, 2 h before collecting.

Chromosome preparations were made by the air-drying method, stained with aceto-orcein and photographed. These were coated with Kodak 'AR-10' stripping film, exposed for 4-6 days, processed and re-stained with Giemsa.

Only  $Ph^1$  + ve diploid and polyploid cells were found in the bone marrow, the number of  $Ph^1$  chromosomes corresponding to the ploidy of the cell. The mitotic index rose slightly from 24 to 72 h in culture. In cultures incubated with tritiated thymidine for 3 h there were no labelled mitoses. After 6 h incubation 60 per cent of mitoses were labelled. In both diploid and polyploid cells incorporating tritiated thymidine at the end of S, the Y or Y's were always heavily labelled in comparison to the 4 G group chromosomes, that is ( $Ph^1$  + 3, 21/22 chromosomes). It was impossible to count the grains over this heavily labelled Y while that over any G group chromosome never exceeded 10 grains. The  $Ph^1$  chromosome appeared to be a member of the later labelling G group pair. In tetraploid cells there was some evidence from grain counts of an asynchrony in synthesis between the 2 diploid complements and between the 2 tetraploid complements in 1 octoploid cell.

**Peripheral blood.** Leucocyte cultures were set up by a modification of the technique of Moorhead *et al.*<sup>3</sup>, with and without phytohaemagglutinin. Preliminary experiments indicated that when a single dose of tritiated thymidine was given, both the number of labelled mitoses and the uptake by the chromosomes were low after a 6-h exposure period. This may be due to the fact that chronic granulocytic blood causes a rapid degradation of tritiated thymidine<sup>4</sup>. A total dose of 2  $\mu$ Ci/10 ml. culture was therefore administered in 0.5  $\mu$ Ci aliquots over a period of 1 h. 6 h before collecting, colcemid being added 2 h before. By this method both the number of labelled mitoses and the thymidine uptake were augmented.

The peripheral blood cells incorporating tritiated thymidine at the end of S were classified according to

## HEATHWAY FOR GLASS WORKING LATHES

A 6½ bore lathe of the latest design with foot drum control

All the HEATHWAY range of lathes have the following features

- ★ Robust construction and lasting accuracy
- ★ Efficient variable speed and easily accessible controls
- ★ Smooth traverses essential to good glassworking

May we send you details of our range of lathes and equipment

the labelling pattern of their *G* group chromosomes. Only those cells could be used in which some, rather than all or none, of the *G* group were labelled. Thus, of a total of 60 cells analysed, 34 provided information.

In one cell of (A. C.) the  $Ph^1$  alone of the *G* chromosomes was labelled (that is, indicating the  $Ph^1$  to be a member of the later synthesizing *G* pair), while in two cells 2 intact *G* chromosomes only were labelled (that is, indicating the  $Ph^1$  to be a member of the early synthesizing *G* pair).

In (J. S.) the  $Ph^1$  was a member of the later pair in 8 cells, of the earlier in 4 cells. In (V. C.) the  $Ph^1$  was a member of the later pair in 7 cells, of the earlier in 12 cells. Thus the  $Ph^1$  did not appear to belong constantly to either the earlier or the later synthesizing pair in any patient. In (V. C.) cultures grown with PHA produced a mixed population of  $Ph^1 + ve$  and  $Ph^1 - ve$  cells. The latter, presumably lymphocytes, were more heavily labelled than the  $Ph^1 + ve$  cells with fewer unlabelled chromosomes and the *G* group separated into 2 heavily labelled and 2 lightly or unlabelled chromosomes.

**$Ph^1$  chromosomes.** In order to compare the pattern of synthesis of the  $Ph^1$  chromosome with that of its intact homologue, it is necessary to be able to sort the other 3 *G* group chromosomes into a pair and an odd one on purely morphological criteria. Gilbert *et al.*<sup>1</sup> do this on the principle that chromosome 21 has the larger size and is satellited. In none of the 3 cases presented here was there considered to be a sufficient, morphological, difference between the three intact *G* chromosomes to warrant the selection of a pair among them. Therefore a statistical comparison of the grain count over the  $Ph^1$  chromosome and its homologue was impossible. Furthermore, at the end of *S* period, the grain count over any *G* chromosome is very low. Thus the method of classifying cells by how many of their *G* chromosomes were labelled was adopted. It was assumed that in cells with a late, heavily labelled, sex chromosome those chromosomes that were unlabelled had completed their DNA synthesis before the addition of tritiated thymidine.

The possible significance of very late *S*-period labelling patterns has been pointed out by German<sup>2</sup>.

The results presented here may be interpreted variously. The  $Ph^1$  chromosome could not be consistently classified in any patient as a homologue of either the earlier or the later synthesizing pair of the *G* group. Thus, if it is accepted that in normal cells autosomal pairs synthesize synchronously, either this synchrony has been upset by the chromosomal deletion, and the  $Ph^1$  varies as to what moment it completes its DNA synthesis, or the  $Ph^1$  may not always belong to the same pair. Such an interpretation cannot but be tentative. The possibility of asynchrony in synthesis between the homologues of a normal pair of chromosomes at the end of *S* period cannot be excluded. However, it would seem important to question the general assumption that the  $Ph^1$  chromosome is always derived from the so-called pair 21.

**Length of *G*<sub>2</sub> period.** It was found that an incubation period of 6 h with tritiated thymidine was necessary in all cases to obtain sufficient numbers of mitoses labelled at the end of *S* period. This indicates a longer minimum *G*<sub>2</sub> period for  $Ph^1 + ve$  cells than the 3.5–4.5 h found for normal lymphocytes in this laboratory. Further evidence of this was provided by the mixed population of  $Ph^1 + ve$  and  $Ph^1 - ve$  cells found in (V. C.);  $Ph^1 - ve$  cells appeared to have been labelled earlier in *S* period than the  $Ph^1 + ve$  cells in the same culture. Peripheral blood cultures of (A. C.) (producing only  $Ph^1 + ve$  cells) incubated with tritiated thymidine for 4, 6, 8 h had respectively 3, 60 and 90 per cent labelled mitoses. However, even in cultures collected 12 h after addition of tritiated thymidine, cells late in *S* were found, indicating a very variable length of *G*<sub>2</sub> period.

**Survival of  $Ph^1$ .** Attempts to discover how many times a  $Ph^1 + ve$  cell will divide *in vitro*<sup>3</sup> were unsuccessful.  $Ph^1 + ve$  cells were, however, found in unlabelled

peripheral blood and bone marrow cultures of (A. C.) after 5 days.

The mitotic index of (A. C.)'s bone marrow was highest at 72 h. In peripheral blood cultures from all 3 patients, grown with or without PHA, 72 h was again the time of highest mitotic index of  $Ph^1 + ve$  cells. Thus it seems that the  $Ph^1 + ve$  cell does persist *in vitro* and that, contrary to Tough *et al.*<sup>4</sup>, the mitotic index for this sort of cell is in some cases higher after 72 than after 24 or 48 h in culture.

**Late-labelling X.** Direct cytological evidence for random inactivation of the maternal or paternal X chromosome<sup>5</sup> was obtained from (V. C.). The late-labelling X was either a small, metacentric, size (10–12) chromosome, or a longer, sub-metacentric, size (6–8) chromosome. Of 20  $Ph^1 + ve$  cells with a late-labelling X chromosome, 9 cells could be assigned to the former group and 11 cells to the latter.

These preliminary investigations indicate that: (1) The  $Ph^1$  chromosome does not appear to terminate synthesis consistently as either an early or a late synthesizing *G* chromosome. Possible explanations are that the deletion has affected its pattern of synthesis or that the  $Ph^1$  might vary as to whether it is a chromosome 21 or 22. (2) A minimum time of 6 h incubation with tritiated thymidine was necessary to obtain labelled  $Ph^1 + ve$  cells in both blood and bone marrow cultures. The *G*<sub>2</sub> period of a normal, control, lymphocyte culture is by comparison 3.5–4.5 h. (3) The  $Ph^1 + ve$  cell can persist for up to 5 days in cultures of peripheral blood and bone marrow. In all the 3 cases studied, the highest  $Ph^1 + ve$  cell mitotic index was found at 72 h. (4) Two distinct, morphological, forms of late-labelling chromosome were found in the  $Ph^1 + ve$  cells of one patient. It is suggested that this was due to random inactivation of maternal or paternal X chromosome.

I thank Dr. S. D. Lawler for her advice and the consultant staff of the Royal Marsden Hospital and the Royal Free Hospital for providing material.

## Low-alkaloid Mutants of *Lupinus digitatus* Forsk

THE Western Australian blue lupin, which has been variously referred to in the literature as *Lupinus pilosus* L.<sup>1,2</sup>, *L. varius* L.<sup>3</sup> and *L. digitatus* Forsk<sup>4</sup>, occurs as a naturalized exotic in west coastal areas of south-western Australia where the annual rainfall exceeds about 16 in. It grows prolifically on coastal sandy soils overlying limestone, and is also cultivated to some extent in adjacent inland areas on slightly acid sands for soil improvement and sheep feed.

Because of its known adaptation to sandy soils of low fertility, its high seed-yield and the high (30–35 per cent) protein content of its seeds, *L. digitatus* would appear to hold possibilities of development as a grain legume for cropping purposes. However, this has been precluded by a number of wild characteristics of the species, including late maturity, hard seededness, shedding of the seeds as soon as they are ripe, and the presence of alkaloids in the seeds and other parts of the plants. The alkaloids, besides being somewhat toxic, render the seeds unpalatable to all classes of stock except possibly sheep.

Naturally occurring low-alkaloid ('sweet') mutants, which are fully palatable and apparently non-toxic<sup>8</sup>, have been selected in *L. angustifolius* L. and *L. luteus* L. by von Sengbusch<sup>8</sup>, who found five mutant plants among a field population of some 1.5 million. Subsequent searches yielded similar mutants in several other lupin species. There appeared to be no reason, therefore, why homologous mutants could not be isolated from field populations of *L. digitatus*.

A search in 1961 among some 220,000 plants, using Dragendorff's reagent paper for spot testing, failed to disclose any low-alkaloid mutants. It was then decided to try artificial mutation methods. Dry scarified seeds of an early-maturing strain of *L. digitatus*, itself an X-ray-induced mutant<sup>9</sup>, were soaked in 0.3–0.4 per cent ethyl methanesulphonate (EMS) at 20° C for 12 h, and sown in the field in May 1962. The progenies of surviving plants were grown the following year and tested for alkaloid content.

Out of 440 progenies, 11 contained mutants which, on the basis of Dragendorff reaction and taste, could be classified as sweet. These have been confirmed in the *M*<sub>1</sub> generation, although strictly quantitative estimates of alkaloid content have yet to be made. Of the 11 types, 7 appear to be associated with reduced vigour or fertility disturbances or both. However, 4 appear, from *M*<sub>1</sub> and *M*<sub>2</sub> observations, to be normally vigorous, and to have normal or nearly normal fertility. Genetic studies of all the more promising mutants are in progress, together with further selection within lines for vigour and fertility.

The success of artificial mutagenesis in producing low-alkaloid mutants in *L. digitatus*, as in producing low-coumarin mutants in *Melilotus albus*<sup>8</sup>, further attests the usefulness of this method in practical breeding. We would like to direct particular attention to its place in the domestication of wild or semi-wild species. In these species there is seldom much natural genetic variation available to the breeder, except as a result of extensive plant exploration. At the same time the kinds of characteristics he seeks, such as reduced seed shedding or freedom from toxic factors, are precisely those which would be selected against in the natural environment. On the other hand, they are usually due to genetically recessive 'loss' factors, and as such should be fairly readily induced artificially by mutagenic agents.

## VIROLOGY

### Transport of S-Antigen of Sendai Virus as revealed by means of Antibody labelled with an Organic Mercury Compound

It has been shown that replication of RNA<sup>1</sup> and synthesis of S-antigen of Sendai virus occurs in nucleolar structures while synthesis of V-antigen occurs in the perinuclear zone of cytoplasm<sup>2</sup>. In later stages of infection both components, ribonucleoprotein (RNA + S-antigen) and haemagglutinin (V-antigen), accumulate in the peripheral zone of cytoplasm where mature virions are formed. A modification of the immunofluorescence

method<sup>3</sup> has revealed the details of synthesis of protein components of Sendai virus, but failed to reveal the details of transport of S-antigen through the territory of nucleus and cytoplasm because it was insufficiently sensitive. Therefore a more sensitive method of detection of S-antigen of Sendai virus was used, namely, antibody labelled with an organic mercury compound, para-aminophenylmercurylacetate (pAPMA)<sup>4</sup>.

Normal non-infected cells treated with virus-specific pAPMA labelled antibody showed only a feeble non-specific contrast due to osmium fixation (Fig. 1), being a good background for a sharp specific contrast due to pAPMA labelled antibody bound with viral S-antigen.

S-antigen appeared in nucleoli 3 h after infection of the cells with the virus and accumulated in considerable amount by 6 h. Optically dense masses appeared as granules, threads and less-rectangular formations, the latter depending on the plane of the ultra-thin section. However, their diameter did not exceed 200 Å, which corresponds to the diameter of the helix of nucleocapsid of Sendai virus<sup>5</sup>. By 9–12 h after the beginning of infection nucleoli became empty and masses of the antigen were revealed in nucleus, in nuclear membrane and in cytoplasm (Fig. 2). It is characteristic that no antigen was inside the mitochondria and cytoplasmic vacuoles; this shows that transport of the S-antigen from nucleoli to cytoplasm occurs through the cytoplasmic reticulum. Release of mature virions from the cell can be demonstrated by means of application of whole pAPMA labelled serum (Fig. 3) which contains both S- and V-antibody.

Thus the use of antibody labelled with pAPMA provides the means not only of establishing topography of synthesis of protein components of Sendai virus but also of tracing

Fig. 1. Non-infected monkey kidney cells treated with Sendai virus S-antibody labelled with pAPMA. A feeble contrast of cellular structures due to osmium fixation ( $\times 18,000$ ).

Fig. 2. The same cells 9 h after infection. Amorphous areas of an empty nucleolus, masses of S-antigen in nucleus, in nuclear membrane and in cytoplasm ( $\times 18,000$ ).

### Antibiotic Carry-over in Cell Cultures of Herpes Simplex Virus

Schneerson and Shore<sup>1</sup> reported that herpes simplex virus grown in cell culture was capable of inhibiting the growth of certain strains of bacteria. In a preliminary investigation in this laboratory, attempts to confirm the findings of Schneerson and Shore were successful. This investigation was then expanded to include testing the virus suspensions collected from different cell lines against a wide range of Gram-positive and Gram-negative organisms representing 15 species. In the course of the assays it was noted that the activity of the virus suspension against test organisms produced a sensitivity pattern similar to that of streptomycin or penicillin. It was noted, however, that this antibacterial activity of the virus culture was lost following serial passage through cells cultivated in antibiotic-free medium. In an attempt to explain the loss of antibacterial activity, the hypothesis was formulated that the antibacterial activity might result from antibiotics carried over from the original inoculum. The purpose of this report is to present the results arising from the testing of this hypothesis.

Two strains of herpes simplex virus were kindly supplied by Dr. Malcolm S. Artenstein, Department of Virus Diseases, Walter Reed Army Institute of Research. Strain Hawkins *EWVK*<sub>1</sub>, isolated in rabbit kidney cell culture from a patient's eye, was in its first cell culture passage. It was ascertained that the medium for cell culture routinely contained antibiotics. Strain Taylor was aseptically obtained from a herpetic lip lesion and suspended in an antibiotic-free solution.

The two strains of *Staphylococcus aureus* and the two strains of *Klebsiella pneumoniae* were laboratory stock

strains of confirmed identity and antibiotic sensitivity. Tube cultures of monkey kidney cells, HeLa cells, Eagle's minimum essential medium and the penicillin and streptomycin mixture were purchased from Microbiological Associates, Inc., Bethesda, Maryland. Monkey kidney medium 'B' (Melnick) and calf serum were purchased from Baltimore Biological Laboratory.

Fluid was decanted from cultures of monkey kidney or HeLa cells and the cell sheet was washed three times with Eagle's minimum essential medium to eliminate any residual antibiotics previously present in the cultures. One-tenth ml. of virus suspension or Eagle's minimum essential medium was inoculated into each tube. After adsorption for 30 min, 1 ml. of antibiotic-free medium was added to each tube, and the tubes were incubated at 37° C for 72 or 96 h until distinct cytopathogenicity was evident in cell cultures infected with virus. The cultures were then frozen at -40° C and later thawed in a 37° C water bath to free the contents as testing material. For comparison, a solution of a penicillin and streptomycin mixture was diluted to a concentration of 150 and 15 units per ml., respectively, and distributed into several test-tubes. Prior to use, half the tubes were stored in the refrigerator and the remaining half were treated as if virus suspensions or cell culture fluids were being prepared.

The disk sensitivity test, utilizing paper disks impregnated with the virus suspension, was conducted as described by Schneerson and Shore<sup>1</sup>. The tube dilution test was performed by routine procedures. The results were recorded after incubation at 37° C for 18 h.

Paper disks impregnated with the herpes virus suspensions were used for sensitivity tests against the four susceptible organisms. Results presented in Fig. 1 (4-8) show that virus suspensions of Taylor strain, regardless of the method of preparation, failed to demonstrate any antibacterial activity. Antibacterial activity was demonstrated in *EWVK*<sub>1</sub> strain virus suspension in its second passage, but not in suspensions of subsequent passages (Fig. 1, 1-3).

Fig. 1. Sensitivity test against *Staphylococcus aureus* by paper disks impregnated with various viral suspensions: (1) *EWVK*<sub>1</sub> — second passage of herpes virus *EWVK*<sub>1</sub> in monkey kidney cell culture; (2) *EWVK*<sub>1</sub> — third passage of *EWVK*<sub>1</sub> in monkey kidney cell culture; (3) *EWVK*<sub>1</sub> — third passage of *EWVK*<sub>1</sub> in HeLa cell culture; (4) Taylor strain of herpes virus — first propagation in antibiotic-free HeLa cell culture; (5) Taylor strain — first propagation in antibiotic-free monkey kidney cell culture; (6) Taylor strain — first propagation in antibiotic-free monkey kidney cell culture incubated for 96 h; (7) Taylor strain — second passage, monkey kidney cell culture to monkey kidney cell culture; (8) Taylor strain — second passage, HeLa cell culture to HeLa cell culture; (9) monkey kidney cell culture control; (10) HeLa cell culture control.

Table 1. SENSITIVITY OF TEST ORGANISMS TO VARIOUS PREPARATIONS

<i>S. aureus</i> (2)	0	0	25	15	26	14	29	24	19

\* (1) Prepared from Taylor strain propagated in antibiotic-free HeLa cell culture; (2) second passage of (1) in antibiotic-free HeLa cell culture; (3) Taylor strain propagated in HeLa cell culture in medium containing 150 units of penicillin and streptomycin per ml.; (4) second passage of (3) in antibiotic-free HeLa cell culture; (5) HeLa cell culture in medium containing 150 units of penicillin and streptomycin per ml.; (6) HeLa cell culture in antibiotic-free medium after inoculation with 0.1 ml. of (5); (7) solution of penicillin and streptomycin mixture containing 150 units each per ml.; (8) solution of penicillin and streptomycin mixture containing 15 units each per ml.; (9) solution of (8) but incubated, frozen and then thawed.

Since in its primary passage the Taylor strain virus failed to demonstrate any antibacterial activity, it was important to determine whether a result similar to that with *EWK<sub>1</sub>* strain could be obtained if the primary propagation of Taylor virus was prepared in a cell culture treated with a known quantity of antibiotics. One-tenth ml. of an antibiotic-free solution of Taylor's lip lesion fluid was inoculated into tube cultures of HeLa cells. At the end of the adsorption time, 1.0 ml. of medium containing 150 units each of penicillin and streptomycin was added to each tube. After incubation for 72 h at 37° C, the virus suspension collected was used as starting material and was afterwards propagated in antibiotic-free cell culture. For comparison, the same procedure was applied to a few tube cultures, except that they were first inoculated with 0.1 ml. of saline instead of Taylor's lip lesion fluid. Sensitivity tests were carried out with these two suspensions and with a mixture of penicillin and streptomycin in concentrations corresponding to those present in the virus or cell culture suspension. Results are presented in Table 1 and Fig. 2. Whereas the antibacterial activity is absent in Taylor strain virus suspensions prepared from antibiotic-free cell culture (Fig. 1), it is present in suspensions of the second passage propagated in antibiotic-treated cell culture. Similar results were obtained from virus-free cell culture fluid. Furthermore, the size of the

Fig. 2. Sensitivity test against *Klebsiella pneumoniae*. (1) Prepared from Taylor strain propagated in antibiotic-free HeLa cell culture; (2) second passage of (1) in antibiotic-free HeLa cell culture; (3) Taylor strain propagated in HeLa cell culture in medium containing 150 units of penicillin and streptomycin per ml.; (4) second passage of (3) in antibiotic-free HeLa cell culture; (5) HeLa cell culture in medium containing 150 units of penicillin and streptomycin per ml.; (6) HeLa cell culture in antibiotic-free medium after inoculation with 0.1 ml. of (5); (7) solution of penicillin and streptomycin mixture containing 150 units each per ml.; (8) solution of penicillin and streptomycin mixture containing 15 units each per ml.; (9) solution of (8) but incubated, frozen and then thawed.

zone of inhibition decreased proportionally with the decrease of antibiotic concentration in these materials by passage or dilution (Table 1 and Fig. 2).

Since the results strongly suggest a carry-over of antibiotics, a tube dilution test was carried out to detect whether the virus particles or cell debris exert any influence on the potency of the antibiotics. Four antibiotic-containing solutions prepared as described here were assayed against two organisms. Since the quantity of antibiotics present in all preparations was approximately equal, the results shown in Table 2 indicate a decrease in the potency of antibiotics present in the virus suspension and cell culture fluids, as compared with the pure antibiotic solutions. Similar results were also shown in the disk sensitivity test (Table 1). It is speculated that the virus particles or cell debris might adsorb antibiotic molecules and thus render them ineffective. No further investigation was attempted in this respect.

D, Penicillin-streptomycin mixture incubated, frozen, and thawed as though viral suspension and cell culture fluid prepared.

† — = no growth of organism, + = growth.

In these experiments it has been demonstrated that: (1) the herpes simplex virus does not exhibit any antibacterial activity if it is isolated in antibiotic-free cell culture (Fig. 1); (2) the antibacterial activity of virus suspensions previously in contact with antibiotics results from antibiotic carry-over rather than from any products of virus-cell interaction. The carry-over mechanism can be visualized as follows: If the virus were isolated from cell culture with medium containing antibiotics of a concentration about 150 units per ml., and if 0.1 ml. of the collected virus suspension were inoculated into an antibiotic-free cell culture, the amount of antibiotics carried over by this process would be diluted to approximately 15 units/ml. The quantity of antibiotics will be further reduced 10-fold by each passage. Such a dilution process readily explains why the antibacterial activity exhibited by the herpes virus suspensions decreased on each passage and finally disappeared (Figs. 1 and 2). In addition, the experimental results further indicate the possible reduction of potency of antibiotics present in the virus suspension or cell culture fluid by some unknown mechanism (Tables 1 and 2).

Prior to Schneerson's report, Gan and Warsa<sup>2</sup> reported the isolation of a bacterial lytic factor from the allantoic fluid of embryonated eggs infected with influenza virus. No further investigations were reported by these authors. Whether any antibiotic can be elaborated from a virus-cell system should be an interesting area of investigation. However, the starting material must be known to be free of antibiotics in order to eliminate any confusion resulting from antibiotic carry-over.

## APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

**JUNIOR RESEARCH FELLOW IN PURE MATHEMATICS**—The Registrar, The University, Sheffield (August 4).

**THEORETICAL OFFICER IN THE DEPARTMENT OF ORGANIC AND INORGANIC CHEMISTRY**, to assist the Superintendent of the Laboratory in his duties, which include responsibility for assistant staff, financial and stores administration, buildings and the application of new and existing laboratory techniques and instrumentation—Dr P. Maitland, Secretary of the Faculty Board of Physics and Chemistry, Chemical Laboratory, The University, Lensfield Road, Cambridge (August 4).

**RESEARCH STUDENT** (with a good honours degree in engineering, metallurgy or physics, or expecting to obtain such before 1st October, 1965) for work on surface breakdown friction and wear between unlubricated metal surfaces in sliding contact at speeds up to 250 ft/s.—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (August 6).

**SENIOR LECTURER**; a **LECTURER**; and an **ASSISTANT LECTURER** IN THE DEPARTMENT OF SOCIOLOGY—The Registrar, University of Strathclyde, George Street, Glasgow, G.1 (August 7).

**FELLOW IN THE DEPARTMENT OF STATISTICS OF THE RESEARCH SCHOOL OF SOCIAL SCIENCES**, Institute of Advanced Studies, Australian National University, to engage in some branch of statistical research related to the social sciences, to advise other members of the Research Schools of Sciences and Pacific Studies on sampling and other statistical techniques, and to help in the training of students in such techniques—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 9).

**LECTURER IN COMPUTER SCIENCE** IN THE DEPARTMENT OF MATHEMATICS—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (August 15).

**LECTURER IN THE DEPARTMENT OF MEDICAL PHYSICS**—The Secretary, Royal Free Hospital School of Medicine (University of London), Hunter Street, London, W.C.1 (August 18).

**LECTURERS (2) IN THE DEPARTMENT OF EPIDEMIOLOGY AND PREVENTIVE MEDICINE**—The Secretary of University Court, The University, Glasgow (August 18).

**SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER** (with an honours degree in dairying, agriculture, science or food science, preferably with postgraduate experience in bacteriology) IN THE AGRICULTURAL BACTERIOLOGY DIVISION OF THE MINISTRY OF AGRICULTURE (successful candidate may be required to undertake teaching duties in the Faculty of Agriculture, Queen's University, Belfast)—The Secretary, Civil Service Commission, Stormont, Belfast, 4, Northern Ireland (August 18).

**AGROLOGIST** (with a degree, preferably with honours, in science or agriculture, and some postgraduate experience in experimental techniques), for work mainly on the control of weeds in sugar beet and other arable crops—The Director, Norfolk Agricultural Station, Sprowston, Norwich, Norfolk (August 14).

**CHAIR OF CONTROL ENGINEERING**—The Deputy Secretary, The University, Southampton (August 14).

**LECTURER IN AGRICULTURAL ZOOLOGY**—The Secretary, The University, Aberdeen (August 14).

**LECTURER IN BIOLOGICAL CHEMISTRY**—The Registrar, The University, Manchester, 13, quoting Ref. 140/65/Na (August 14).

**LECTURER** (with a special interest in radio chemistry) IN THE DEPARTMENT OF CHEMISTRY—The Secretary, The University, Aberdeen (August 14).

**SENIOR LECTURER** (honorary consultant status) IN THE DEPARTMENT OF ORTHOPAEDIC SURGERY—The Secretary, The University, Edinburgh (August 14).

**STUDENT (MAN OR WOMAN) IN THE CHEMISTRY DEPARTMENT FOR RESEARCH IN INFRA-RED SPECTROSCOPY**—The Secretary, Royal Holloway College (University of London), Egham, Surrey (August 14).

**RESEARCH FELLOW IN THE SCHOOL OF MATHEMATICAL AND PHYSICAL SCIENCES** to join a research group working on defects of solids; both point defects and dislocations are being studied in a wide ranging programme, which includes the use of an electron microscope with liquid helium stage facilities—The Assistant Registrar (Establishment), University of Sussex, Slammer House, Slammer, Brighton, Sussex (August 15).

**RESEARCH FELLOW** (preferably with research interests in the field of theoretical solid state, nuclear or elementary particle physics) IN THE DEPARTMENT OF MATHEMATICAL PHYSICS—The Assistant Registrar (Science), University of Birmingham, Birmingham 15 (August 15).

**JUNIOR RESEARCH FELLOW IN BOTANY**—The Registrar, The University, Sheffield (August 31).

**SENIOR LECTURER IN MATHEMATICS**; a **SENIOR LECTURER IN STATISTICS**; a **LECTURER OR ASSISTANT LECTURER IN MATHEMATICS**; a **LECTURER OR ASSISTANT LECTURER IN STATISTICS**; a **LECTURER OR ASSISTANT LECTURER IN NUMERICAL ANALYSIS AND COMPUTING**; and a **LECTURER OR ASSISTANT LECTURER IN OPERATIONAL RESEARCH**—The Registrar, Ref. 114Y/H, Bradford Institute of Technology, Bradford, 7 (August 23).

**LECTURER OR ASSISTANT LECTURER IN PSYCHOLOGY** at the University of Otago, Dunedin, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (August 25).

**RESEARCH AGROLOGIST**; a **SENIOR LECTURER/LECTURER IN AGRICULTURAL BOTANY**; a **RESEARCH BOTANIST/PLANT BREEDER**; a **PLANT INTRODUCTION OFFICER**; and a **PLANT PATHOLOGIST** at AHMADU BELLO UNIVERSITY, NORTHERN NIGERIA—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (August 26).

**SENIOR LECTURER IN SURGERY**—The Registrar, The University, Sheffield (August 28).

**ASSISTANT LECTURER** (mathematician with qualifications in probability theory and statistics) IN THE DEPARTMENT OF MATHEMATICS—The Secretary, University of Lancaster, Bailrigg House, Lancaster (August 31).

**EXPERIMENTAL OFFICER** (interested in the design and construction of equipment for a wide range of psychological experiments) IN THE DEPARTMENT OF PSYCHOLOGY—The Registrar, The University, Manchester, 13, quoting Ref. 130/66 (August 31).

**LECTURER** (graduate, with a good honours degree in sociology, anthropology, or rural sociology) IN SOCIOLOGY IN THE FACULTY OF AGRICULTURAL ECONOMICS, UNIVERSITY OF NEW ENGLAND, ARMIDALE, NEW SOUTH WALES, AUSTRALIA—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 31).

**SENIOR EXPERIMENTAL OFFICER IN CHARGE OF THE ELECTRON MICROSCOPY LABORATORY**—The Deputy Secretary to the Academic Council, University of Belfast, Northern Ireland (August 31).

**SENIOR LABORATORY TECHNICIAN** (with a knowledge of biophysics) IN THE DEPARTMENT OF PHYSIOLOGY—The Assistant Secretary, Royal Veterinary College, Royal College Street, London, N.W.1 (August 31).

**ASSISTANT LECTURER IN BOTANY**—The Secretary, The Queen's University, Belfast, Northern Ireland (September 1).

**LECTURER OR ASSISTANT LECTURER** (graduate in medicine, veterinary science, dentistry or biology) IN THE DEPARTMENT OF HISTOLOGY—The Registrar, The University, Liverpool, quoting Ref. CV/195 (September 1).

**LECTURER IN MATHEMATICS AT THE UNIVERSITY OF NEW SOUTH WALES** (Broken Hill Division)—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 4).

**READER** (with a special interest in either experimental reactor physics, fluid dynamics or heat transfer) IN NUCLEAR ENGINEERING AT QUEEN MARY COLLEGE—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 13).

**KEMPER** (with museum experience, a British university degree or equivalent, and preferably the Diploma of the Museums Association) OF THE DEPARTMENT OF NATURAL HISTORY—The Director, City Museum and Art Gallery, Congreve Street, Birmingham 3 (September 20).

**LECTURER** (with a degree in pure science or agricultural science, and taken zoology to an advanced level) IN AGRICULTURAL ZOOLOGY at Lincoln College (University of Canterbury), New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 25).

**MYCOLOGIST** (with a good honours degree) to work on soil-borne diseases of cereals—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (September 30).

**ASSISTANT LECTURER** (with a degree in physiology, pharmacology or pharmacy) IN THE DEPARTMENT OF OPHTHALMOLOGY—The Academic Registrar, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

**BIOCHEMIST** (national of, and permanently resident in, the United Kingdom or the Republic of Ireland, with an honours degree in biochemistry or Associatehip of the Royal Institute of Chemistry, and at least two years postgraduate experience in medical biochemistry in a hospital laboratory) in Uganda, to take charge of the Biochemistry Division of the Laboratory services located in Kampala and serving all parts of the country and all races—Appointments Officer, Ministry of Overseas Development, Room 404, Strand House, Stag Place, London, S.W.1, quoting Ref. RC/206/183/06.

**CHAIR OF CHEMICAL ENGINEERING**—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 32/G.

**POST-DOCTORAL FELLOW IN SOLID STATE PHYSICS** for work on the transport and optical properties of molecular crystals—The Registrar, The University, Leicester.

**POST-DOCTORAL FELLOW IN THE DEPARTMENT OF PURE AND APPLIED CHEMISTRY**, to assist Prof. M. Gordon in fundamental studies on new reproducible covalently linked gels, rubbers and highly branched liquids—Prof. M. Gordon, University of Strathclyde, George Street, Glasgow, G.1.

**PRINCIPAL SCIENTIFIC OFFICER** (with a good honours degree in a biological subject and considerable experience in ecological research), to assist in the scientific administration of the Council's activities, with particular responsibility in the biological field—The Natural Environment Research Council, Establishments Division, State House, High Holborn, London, W.C.1.

**RESEARCH ASSISTANT** for investigation of the chemistry of carboxylase and other metallo-proteins—The Secretary, Chemical Pathology Department, St. George's Hospital Medical School, London, S.W.1.

**RESEARCH ASSISTANT** (with a Ph.D. or B.Sc. or equivalent in chemistry, mathematics or physics, and interested in the application of computer techniques to molecular theory) IN THEORETICAL CHEMISTRY—The Secretary, Royal Holloway College (University of London), Egham, Surrey.

**RESEARCH FELLOW OR SENIOR RESEARCH FELLOW** (graduate or equivalent, with several years of research experience in ferrous metallurgy, and preferably a knowledge of electron microscopy and fracture mechanics) IN THE DEPARTMENT OF MATERIALS, to participate in a research programme supported by the Science Research Council, into the relationship between metallurgical structure and properties in the weld heat affected zone in low alloy steels, with particular reference to brittle fracture resistance—The Registrar, The College of Aeronautics, Cranfield, Bedford.

**RESEARCH STUDENT IN GEOGRAPHY**—The Registrar, The University, Hull.

**SCIENTIFIC OFFICER OR SENIOR SCIENTIFIC OFFICER** (honours graduate, preferably in chemistry, agricultural chemistry or biochemistry) IN THE CHEMISTRY DEPARTMENT, to take part in a research programme on ruminant nutrition concerned mainly with the relationship of the feeding, digestion and metabolism of the cow to the secretion of fat, protein or lactose in milk—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 65/N/10.

**SCIENTIFIC OFFICER** (with a good honours degree in biochemistry or chemistry, and with a particular interest in lipid metabolism) to investigate the interrelationship between sterol and fatty acid metabolism in animals—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 65/N/11.

**SENIOR ANIMAL TECHNICIAN** (male, 25 years of age or over, and at least an Associate of the Animal Technicians Association, and experience or interest in BFF and germ-free techniques) for interesting work in modern, well equipped laboratory animal houses—The Director, Laboratory Animals Centre, M.R.C. Laboratories, Woodmansterne Road, Camberley, Surrey.

**SENIOR LECTURER** (veterinary graduate with postgraduate qualifications or an honours graduate with a science degree majoring in anatomy and physiology or biochemistry) IN ANIMAL HUSBANDRY (Meat Production) at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1.

**SENIOR RESEARCH ASSOCIATE IN THE SCHOOL OF CHEMICAL SCIENCES** for work in the preparation and spectroscopic study of disymmetric aromatic molecules or coordination compounds—Prof. S. F. Mason, School of Chemical Sciences, University of East Anglia, Wilberforce Road, Norwich, NOR 77H.

**S.R.C. POSTDOCTORAL FELLOW** (spectroscopist, physicist or physical chemist) for a research project (already partially completed) concerned with the scattering of light in liquids and gases using a laser source—Dr. A. J. Hyde, Department of Pure and Applied Chemistry, University of Strathclyde, George Street, Glasgow, G.1.

## A SOCIAL SCIENCE RESEARCH COUNCIL

THE Committee on Social Studies was set up with Lord Heyworth as chairman in June 1963 "to review the research at present being done in the field of social studies in Government departments, universities and other institutions and to advise whether changes are needed in the arrangements for supporting and co-ordinating this research". Its principal recommendation is for the establishment of a Social Science Research Council to provide support for research, to keep under review the state of research and the supply of trained research workers, to advise the Government on the needs of social science research, and to give advice on research in the social sciences and its application. Such a Council was recommended in 1961 in a report from the British Academy (*Nature*, 193, 1011; 1962), also in 1962 in a memorandum by Prof. D. V. Glass and Prof. M. Gluckman submitted to the Robbins Committee by the British Association (*Nature*, 196, 704; 1962), and more recently in a paper of the Council of the Tavistock Institute of Human Relations (*Nature*, 205, 729; 1965). This time, however, the recommendation has been accepted by the Government, although details are still under consideration. However, it is rather curious that in a historical survey of the field since 1945 the report now issued by the Committee on Social Studies of the Department of Education and Science\* merely refers to the report of the Clapham Committee in 1946 and its recommendation for an Interdepartmental Committee of Social and Economic Research. The Interdepartmental Committee has not met since 1960 although it is still formally in existence: most of the departments giving evidence to the Heyworth Committee appeared to be unaware of its existence.

In considering the scope of the social sciences, which are regarded as including economics, politics, sociology, demography, social anthropology, social administration and social psychology, the Heyworth Committee draws a distinction between research and fact-finding, the former being regarded as something other than routine fact-finding, or fact-finding for specific administrative purposes. While the distinction is sometimes difficult to draw, it is important to make the attempt if the need for social research is to be assessed accurately and is to be soundly based. The Committee is also wise to emphasize the importance of research in the social sciences to the administrator. Unless an attempt is made to identify long-term problems or penetrate behind everyday decisions, those decisions may be based on wrong or inaccurate data. Whether he knows it or not, anyone engaged on administration in central or local government, in education or in commerce and industry is using methods and techniques to help him deal with his work and solve problems that a social scientist would recognize. It only strengthens the Committee's argument that the use of the computer is allowing decisions to be based on facts to a scale impracticable even a decade ago.

\* Department of Education and Science. *Report of the Committee on Social Studies*. Pp. v+101. (Oxford 1960) (London: H.M.S.O., 1965.) 7s. 6d. net.

Looking next at developments since 1945, the Heyworth Committee estimates that between 1938-39 and 1962-63 the number of university teachers in the social sciences increased from 212 to 1,025, while the number of students obtaining honours degrees in the social sciences also increased five-fold, from 300 to 1,537; since 1959-60 the percentage of full-time students in social science faculties has risen from 10.5 to 11.4 in 1962-63 and 12.1 in 1964-65. In addition, home registrations for external London degrees in sociology have increased from 40 in 1952-53 to 217 in 1963-64 and 460 in 1964-65. Moreover, the Committee formed the impression that a larger proportion of abler students is now entering the social sciences. The rate of growth is not uniform over all the subjects. Thus, while sociology has recently grown explosively, growth in psychology has been largely on the biological side and social psychology has been neglected in British universities compared with its development in the United States, nor is there any centre encouraging the study of law as a social science. Again, while the number of postgraduate State studentships awarded in the humanities and social sciences remained fairly constant at about 250 during the years 1957-61, the number increased in 1962 when 304 were awarded in the humanities, 48 in the social sciences and 95 in related disciplines, compared with 1,607 in science and technology; for 1964 the corresponding figures were, respectively, 626, 184, 190 and 2,453.

The universities are still the main centres for research in the social sciences, and the Committee is satisfied that since 1946 the social sciences have become firmly established in the universities and that a basis has been laid for the future supply of teachers and research workers. Total expenditure by the universities on research in 1962-63 is estimated at £1,575,000 with a further £160,000 from Oxford and Cambridge College funds and endowments, £884,000 from external sources and £300,000 on agricultural economics. Expenditure by research institutes outside the universities, notably by the Tavistock Institute of Human Relations (£170,000), the National Institute of Economic and Social Research (£79,000) and the National Foundation for Educational Research (£35,000), is estimated at £577,000, and for the three Institutes named the expenditure for 1964-65 is put at £220,000, £94,000 and £103,000, respectively. Expenditure by Government research organizations (£780,000) and Executive Departments (£220,000) and overseas (£90,000) at Colleges of Technology (£100,000) and by other bodies and individuals brings the total for 1962-63 to about £5 million, and for 1964-65 the figure is likely to be about £6.5 million.

The Committee attempted to estimate the distribution of this research effort over different fields, but it was only able to do so for some 70 per cent of the total and drew no firm conclusions. Of this 70 per cent, 16 per cent seems to be spent on health and welfare, 14 per cent on industry, 11 per cent on education, 10 per cent on agriculture and

9 per cent each on the general British economy and on developing countries, including race relations, etc. While industry and commerce are taking more graduates in the social sciences and increasing their share of the output, the Committee formed the impression that industry made little use of social scientists in research within its own organization and did not employ them where they would be led to identify problems requiring research and give advice accordingly. Most voluntary associations complained of the difficulty of finding even small sums to finance research and of discovering what research of a similar nature was being undertaken elsewhere. Again, although substantial numbers of social scientists are employed by local government, new town development corporation and other statutory bodies, they are seldom engaged on research. Local Authorities' Associations seem to realize the value of social science research, but this awareness is as yet unaccompanied by a substantial increase in the support or direct contracting of research.

In the Government service the employment of economists and psychologists professionally has been increasing and nearly all departments now employ statisticians. However, the Committee gained the impression that very few sociologists and other kinds of social scientists are employed in departments in a professional or advisory capacity, and that until a few years ago there had been little growth in research in Government departments since the Clapham Committee reported. In June 1964 the National Economic Development Council was employing 20 economists and one sociologist, some of whose work could be described as research, and had arranged for work on contract in university departments. In 1964 the Board of Trade established an economic research unit and research has been strengthened in the Ministry of Housing, the Scottish Home and Health Department and the Ministry of Public Building and Works, although some of this effort is fact-finding rather than research.

This section of the Heyworth Report gives a sidelight on the effect of the premature dissolution of the Overseas Research Council. When in 1962 the Department of Technical Co-operation took over the disbursement of finance for social science and other overseas research the Colonial Social Science Research Council and the Colonial Economic Research Committee were abolished. From 1958-59 to 1962-63 they had contributed £260,000 towards the general running costs of research institutes in colonial territories, £97,000 as grants for specific projects requested by Colonial Governments, £64,000 as grants for projects requested by the Colonial Office or one of the advisory bodies, and £31,000 as grants to individuals for field research in colonial territories. As already noted, it is estimated that in 1962-63 some £90,000 was expended from Government funds in support of research in dependent territories overseas, and in addition to this the Committee estimates that £136,000 went to the developing countries from university research funds and £157,000 from the research institutes.

In the second part of the Report the Committee discusses the need for more research in the light of this situation. Successive chapters deal with the supply and training of research workers, the organization of research and the use of research, leading up to the recommendation for the establishment of a Social Science Research Council and the issues involved in this recommendation. While the Report lists numerous problems suggested to the Committee as needing attention, no comment is made other than the observation that almost all the problems involve contributions from one or more of the social

sciences and often from disciplines outside them. This has a close bearing on the supply of research workers; the Committee considers that the first priority is a further expansion of postgraduate training in the social sciences. It suggests that the 220 awards for postgraduate study in 1964 should be increased to 400 in 1965-66, particularly in sociology and social psychology, with a further increase in 1966-67. It also recommends that at least 20 research fellowships should be available in the social sciences in 1965-66 under the scheme hitherto run by the Department of Scientific and Industrial Research, and not necessarily tenable only in a university but also in a research institute, a Government research station or other research organization.

While it recommends priority for postgraduate studies, it emphasizes also the importance of research assistants, and suggests that married women who are prepared to return to full-time work after bringing up their families should be enabled to enter the research field. Furthermore, it recommends that universities need to examine not only the organization of teaching and research duties in social science departments but also the method of allocating funds for auxiliary staff and facilities for research. It foresees a substantial demand for teachers of the social sciences in the technical colleges, and emphasizes the importance of giving such teachers opportunities to be associated with research. Similarly it directs attention to the importance of utilizing the capacity for training of research institutes outside universities, including the Social Survey of the Central Office of Information and research units in Government departments. However, it urges that expansion of postgraduate training would be carried out most effectively and economically if a few places are built up as research schools.

It is in keeping with the general balance and sanity of the Report that the Committee recognizes the importance of being able to offer reasonable prospects of a career if sufficient able recruits are to be attracted to study the social sciences. The Committee does not consider that many people would be best employed in one institution during their professional career in social science research, but this is not the only reason which it advances in recommending flexible arrangements by the universities as regards teaching duties and research. It is desirable that many who continue to pursue research throughout their career should be able to move from one institution to another. For this reason alone the Committee is on firm ground, with authoritative opinion elsewhere behind it, in wishing to see a range of research posts in universities, units attached to universities, independent research institutions, and Government research establishments, subscribing to a common policy of interchangeable pension rights and seniority grading, and of secondments.

Beyond this, however, if research workers in the social sciences are to have the assurance of a satisfactory career which the evidence submitted to the Committee suggests they often lack, it will be necessary to create more established posts for those qualified in the social science disciplines and trained in the methods of research. Full-time research, however, will often be only a phase, perhaps to be repeated, in the career of men and women who, in other phases, will be university teachers, managers, administrators in the Civil Service or local government, professional economists, sociologists or psychologists, etc. This is another reason for recommending a common policy in pension rights, seniority grading and secondment to encourage and facilitate the necessary mobility and interchange, nor should interchange between the Civil Service

and industry present as much difficulty here as it sometimes does in other spheres. It is also desirable as contributing to meeting the two needs which, the Committee suggests, have to be overcome before we can expect the results of research in the social sciences to be applied effectively.

The first of these is for administrators and managers to be familiar with the scope and value of the social sciences, not only as direct aids to administration but also as disciplines which can limit the uncertainties within which decisions have to be taken and which can evaluate their outcome. Clearly this will be facilitated as interchange grows. However, because problems rarely present themselves to administrators in a fashion which at once shows how they could be clarified by research in the social sciences, there is, secondly, a need for social scientists to work at points where problems first emerge and to help identify and deal with them: this in itself is a reason for encouraging mobility. As the Committee observes, in expressing their research needs and in constructing research units or divisions, user organizations must bring social scientists in a close working relation with administrators.

This is the more important in that in the social sciences, when full allowance is made for the difference in the nature of applied research, there are very few people whose functions correspond to the engineering or development function in the physical sciences, and nowhere are such people trained. This gap needs filling and the Committee remarks that the training given to people to fill this function should include a basic grounding in business economics and also practice in co-operating in research with people trained in other disciplines. It is in connexion with the use of social research that the Committee is anxious to see more social scientists, other than economists, employed in the Government service not only for the research they will do but also because they will help departments to identify the problems to which research in the social studies can contribute, and to track down research already undertaken and apply it to administrative use.

The Committee was asked by the then First Secretary, Mr. R. A. (now Lord) Butler, to comment on the desirability of units of social research in the Departments of Health, Housing and Local Government, Labour, Pensions and National Insurance, and of a unit for demographic research attached to the Central Statistical Office. After pointing out that if the findings of research are to be brought most effectively into the administrative process, professionally qualified staff with experience of research in the discipline concerned must be associated with administrative officers as members of a team. There is, however, need for some central point in the department for the professional social scientists, where day-to-day work is in the various branches. Beyond this, the Committee is content to point out that whether better results would be obtained from a special research unit operating within the department rather than from a programme of research contracts depends on various factors, six of which it specifically indicates, and rather than make specific recommendations it leaves departments to make their own decision in the light of such considerations.

It is at this point that the Committee approaches the question of central organization and interdepartmental action. Its suggestions here are made on the assumption that a Social Science Research Council such as it recommends will, in fact, be established. First it suggests

that the syllabus of the training courses at the Centre for Administrative Studies in the Treasury should include all the social sciences that have a contribution to make to administration. It also recommends that the Treasury should review the conditions of employment of social scientists in the Government service and undertake a central scrutiny of departmental budgets for research for their own purposes: this could usefully be supplemented by consultation with the Social Science Research Council. Better, fuller, more co-ordinated and earlier Government social statistics are needed, especially if their value as a basis for research is to be improved. Here the Central Statistical Office should take the lead, but the link between Government and social scientists outside the Civil Service should be forged through the Social Science Research Council. Dissolution of the Interdepartmental Committee on Social and Economic Research is recommended and also the transfer to the Treasury of the Social Survey, which is at present inefficiently used. The programme of the Survey should be determined by a Committee, under Treasury chairmanship, of representatives of the main user departments and of the Social Science Research Council.

The Committee's observations about the needs of the Government apply in principle to local authorities, statutory bodies, industry and commerce, the judicial system and other users of research: it is against this background that its proposal for a Social Science Research Council should be considered. It rejects the idea of separate research councils for education and the 'built environment'. It considers that the needs of education will best be met by establishment of a Board within the orbit of the Council. Likewise, the needs of planning will be met by establishment of a joint board by the Research Councils concerned with technology, the physical sciences, the arts and the social sciences—presumably after consultation with the bodies which have already constituted a Land Use Research Trust and with specially interested departments of Government.

The Social Science Research Council should consist of an independent chairman and about ten or twelve members, mainly social scientists, but some with experience in industry or 'user organizations', appointed by the Secretary of State for Education and Science, and the Central Government should be represented on the Council and its Committees by assessors. If the Council is brought within the system under which the Council on Scientific Policy advises on the allocation of resources among the Research Councils, the membership of the latter Council should include one or more persons with an up-to-date knowledge of the needs of the social sciences. An expenditure of some £800,000 during the first year is contemplated and £1,000,000 during the second, rising to £2.25 million in the third year, but these figures include some existing expenditure on studentships and research fellowships and on research grants. Existing commitments for research grants are estimated at £170,000 in 1965-66 and £190,000 in 1966-67, but commitments totalling £1 million in the first year and £1.5 million in the second are recommended over varying periods and the figure of £1.5 million is unlikely to be approached until the fourth year.

The recommendations of the Heyworth Committee on finance are subject to review and, in any event, the Government has not yet committed itself on finance beyond accepting the need for some increase in financial support for social science research. It has also not accepted the proposal for a joint board of the various Research

Councils to cover research in the field of urban planning, and it is considering what alternative provision should be made. It is noteworthy that the Committee expresses no opinion as to the ultimate level which expenditure on social science research should reach, although the Council of the Tavistock Institute of Human Relations in 1964 envisaged an expenditure of £25 million by 1980. Its estimate of present expenditure was, however, only £3.5 million a year compared with the £8.5 million in the Heyworth Report.

There are two other points which are important. The Heyworth Committee had reservations as to the value of a register of research in the human sciences such as is at present put out by the Warren Spring Laboratory, but it suggests that the new Research Council should consider whether it should take over this register and extend it to cover the whole field of social sciences. The Committee has no hesitations, however, as to the second point relating to library facilities. Clearly the question of inadequacies in university library facilities for social science must await the report of the Committee considering the needs of university libraries generally. Nevertheless, the Heyworth Committee is satisfied that a strong case exists for providing lending library facilities for the social sciences along the lines of those providing for technology and the natural sciences by the National Lending Library at Boston Spa. It proposes that the Department of Education and Science should arrange for a study to be made of the feasibility of extending these facilities to include the social sciences.

That proposal may merit examination, but it is a less straightforward proposition than might appear at first sight. It requires examination in the light of the library services of the whole country: it should be remembered that in his presidential address to the Library Association last May, Sir Frank Francis insisted that as yet Britain has no library system as such. To create such a system is one of our primary needs, and the dilatoriness over the creation of the new Reference Library for Science and Invention illustrates the absence of any sense of urgency on the part of the Government.

It is one of the merits of the Heyworth Report that it directs attention to the importance of such ancillaries to research. There is no suggestion that, by itself, the creation of a Social Science Research Council—or even a larger supply of men and women trained in the social sciences and techniques of research—will solve our difficulties, nor even that more finance is the first need. The problem is seen as a whole, and if the Government has accepted the recommendation for a Research Council it remains for informed opinion to see that the Research Council is adequately supported and that its work is not hampered by failure to implement the numerous other recommendations on which the effectiveness of the Council largely depends.

## FESTSCHRIFT FOR HAROLD C. UREY

### Isotopic and Cosmic Chemistry

Edited by H. Craig, S. L. Miller and G. J. Wasserburg. Pp. xxv + 553. (Amsterdam: North-Holland Publishing Co., 1964.) 108s.

THE custom of the festschrift has never firmly established itself in the English-speaking countries, although from time to time such a compliment is paid to some outstanding scientist. For the publication to appeal

to a variety of readers, many of whom cannot have had the good fortune to meet the recipient, it is necessary that he should have breadth of interests, a versatile and enquiring mind and, above all, originality in his ideas. In addition, it is helpful if he has taught and inspired a succession of pupils and collaborators, since they may be expected to initiate the production and contribute substantially to its success.

Prof. Harold Urey undoubtedly fulfils these criteria. The career of such a dynamic personality is never dull. "The present volume of contributions cannot hope to match the complete range of topics he has enriched, but almost every paper bears his mark to a greater or lesser degree." It is remarkable to discover that he first graduated in zoology before the First World War. Both the First and the Second World Wars profoundly affected his life and interests. The First led him to chemistry and confirmed his intention to enter academic life; in the Second he played an important part in the Manhattan project and it eventually led to his moving from Columbia to Chicago.

Urey spent a short period at Berkeley at the peak of G. N. Lewis's career, and although the precise effect of this interlude is only a matter of speculation, undoubtedly Urey has remained interested in thermodynamic problems. It is characteristic of both Urey's written and spoken word that he applies a very quantitative analysis even to the most speculative of hypotheses. For several years after this period his principal interest lay in spectroscopy and quantum mechanics. This phase culminated in the collaboration with Ruark in the publication of one of the classics of physical chemistry, *Atoms, Molecules and Quanta*.

Spectroscopy led to an interest in the properties of different stable isotopic species, their separation and abundance. Thus began studies that constitute the central theme of much of his subsequent work and brought him the 1934 Nobel Prize for Chemistry. *Isotopic and Cosmic Chemistry* is extensively concerned with the information that can be gained from measurements of the generally small changes in isotopic composition brought about by natural or laboratory processes.

His earlier interests are represented by two short papers, a note by J. E. Mayer on Loschmidt's paradox and another by A. E. Ruark on classical fields. But the majority of the papers deal with these isotopic effects or with a branch of science that Urey can reasonably regard as his own—cosmochemistry. A part of this subject, the chemical and radiochemical study of meteorites, had indeed been explored for several years by F. A. Paneth, but Urey's work covers a much broader canvas, as can be judged from his book, *The Planets, their Origin and Development*. Urey's insistence on a broad attack—"treating the whole problem"—is another characteristic of his intellectual personality. His interest in this subject, which he has developed rapidly since the Second World War, dates back at least to 1931 when he published a paper in collaboration with Bradley on the origin of the elements, using thermodynamic arguments based on the abundance of the isotopes of the lighter elements.

Among the many interesting contributions may be mentioned three papers dealing with temperature measurements by means of  $^{18}\text{O}/^{16}\text{O}$  ratios. One deals with the application of Urey's original palaeotemperature technique to a series of fossil shells from previously inhabited caves in the Mediterranean area. The other two explore the possibility of extending such temperature measurements to establish the temperature at which oxygen equilibration occurred between different minerals in suitable geological formations—geothermometry. A number of papers treat geochronological measurements; one rather long paper shows how metamorphic processes can invalidate conventional measurements, the data relating especially to  $^{87}\text{Rb}/^{87}\text{Sr}$  measurements.

Seven papers deal with meteorites, their origin, frequency of falls, radiation ages and composition. The longest of these gives a scholarly account of the classification of the chondrites on the basis of their chemical and petrological composition. The abundance of uranium and thorium is discussed in relation to theories of the genesis of the elements, and finally one paper discusses the chemical composition of comets.

All Urey's most speculative interests, the origin of the elements, the planets and life itself are represented. The volume is a worthy tribute to a remarkable man.

A. G. MADDOCK

## GEOLOGICAL AND CHEMICAL EVOLUTION OF EVAPORITES

### Salt Deposits

The Origin, Metamorphism and Deformation of Evaporites. By Prof. Hermann Borchert and Dr. Richard O. Muir. (The University Series in Geology.) Pp. x + 338. (London and Princeton, N.J.: D. Van Nostrand Company, 1964.) 80s.

THIS translation of Hermann Borchert's important book *Ozeane Salzlagernissen* (Geb. Borntraeger, 1959), with a considerable amount of material added by R. O. Muir, the translator, may justly claim to be the first comprehensive work in English on the natural salt deposits, the only previous approach to such a treatment being F. H. Stewart's chapter in the current revision of Clarke's *Data of Geochemistry* (U.S. Geol. Survey Prof. Paper 440-Y. Pp. 52. 1963). It is most valuable to have this summary from one of the leading European authorities, the more so because the deposits of the German Zechstein are considered at some length and these have probably been studied more intensely, and for a longer time, than any in the world.

In the case of the evaporites, as with marine iron ores, the 'principle of uniformity' cannot be applied, in that no extensive marine halite or potash accumulations can be observed in process of formation at the present. The factors controlling development and distribution of salt deposits, past and present, thus have to be inferred from geological evidence, and from the evidence of physical chemistry. After presenting a useful summary of the properties of the 26 important mineral phases found in evaporites, the first five chapters deal with depositional environment, distribution, sedimentation and tectonics, some emphasis being placed on the recurrent rhythmic nature of precipitation. Usiglio's contention that the necessary environment is a basin or series of basins with tectonic bars to control the influx of new sea-water is strongly upheld.

Isothermal evaporation of sea-water is next considered and the paths of crystallization illustrated in terms of the quinary system  $\text{Na}_2\text{O}-\text{K}_2\text{O}-\text{MgO}-\text{CaO}-\text{SO}_4$ . Oceanographic studies show, however, that temperature and concentration gradients exist in all basins, varying with changing current velocities to maintain a dynamic equilibrium. A brave attempt to consider the dynamo-polythermal evaporation of sea-water is therefore made and interesting conclusions are reached about the successive stages in primary facies variation as a basin becomes more isolated from the open sea.

It has long been known that profound mineralogical changes occur in complex salt deposits as they become more deeply buried, arising from the changed temperature-pressure conditions, and from the activity of solutions, especially those being eliminated from deeper levels. Writers in English have hitherto hesitated to describe these changes as metamorphic, since they occur under conditions where silicate minerals in sedimentation are undergoing the changes associated with diagenesis, below the lowest recognized grade of metamorphism. Nevertheless, the authors make a good case for describing the

modifications in the evaporites as metamorphic and show that they can be considered in relation to the phase diagrams for various temperatures in the quinary system mentioned here, rather more effectively than silicates can be deciphered in terms of present knowledge of the physical chemistry of such systems as  $\text{Na}_2\text{O}-\text{K}_2\text{O}-\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$  at elevated temperatures. Chapters 8-15 deal with metamorphism and its consequences; with normal progressive metamorphism described in terms of melting and the activity of melt liquors; and with retrograde metamorphism described in terms of the effects of water eliminated during dehydration reactions at greater depth and forced upward. The latter type of metamorphism is caused by dilute solutions percolating very slowly into salt deposits; besides waters originating as already noted from the conversion of gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ) into anhydrite ( $\text{CaSO}_4$ ) and similar sources, the possibility of activity by hydrothermal solutions of magmatic origin is contemplated, and the well-known solution effects due to meteoric groundwater are also included. Here there are possible grounds for criticism, for changes taking place within the zone of circulating groundwaters do not form part of the silicate petrologist's conception of metamorphism. It must, however, be recognized that it is not easy to avoid this difficulty. The essential distinction between the two types of salt metamorphism proposed is that normal progressive changes are produced by authigenic liquors generated by geothermal melting, and lead to a sequence of mineral associations of which each successive one is in stable equilibrium with a liquid phase that becomes increasingly rich in  $\text{MgCl}_2$ . Retrograde changes, on the other hand, give rise to parageneses stable in brines becoming deficient in  $\text{MgCl}_2$ , but increasingly sulphatic. With the basic conception of salt metamorphism established, it is possible to look at facies variations in the deposit and to attempt to assess their primary or secondary nature; and it is clear that very many have been influenced by post-depositional changes.

A variety of different evaporite districts are described, and there are interesting chapters on the mechanical properties of salts, on salt-tectonics, and on the relationship between evaporites and oil accumulations.

This book is a very important contribution to the literature of the subject, but it is aimed at the advanced student or the specialist, for its authors do not hesitate to enter into controversies the background of which can only be adequately known to those familiar with what has been written during the past two decades about evaporites in several different countries. A less-sophisticated version for the ordinary student of geology or chemistry would also be welcome.

K. C. DUNHAM

## MAGNETISM AND LIFE

### Biological Effects of Magnetic Fields

Edited by Madeleine F. Barnothy. Pp. ix + 324. (New York: Plenum Press, 1964.) 16.00 dollars.

**BIOLOGICAL Effects of Magnetic Fields** is not, as might be supposed, yet another report of a conference attended by workers with a common interest; it is rather a book designed "to provide a theoretical and practical background" for would-be research workers, and also to "bring together in one volume the present-day knowledge in all the active fields of biomagnetic research". It is divided into four main sections: first, "Theoretical Considerations"; secondly, "Effects of Strong Magnetic Fields on Specimens *in vivo*"; thirdly, "Effect of Strong Magnetic Fields on Specimens *in vitro*"; and fourthly, "Effects of Very Weak Magnetic Fields". Finally, there is a fairly comprehensive bibliography relating to the effects of static fields.

On the whole I must confess that I found the book disappointing. Perhaps a failure to achieve some sort of unified

approach should occasion little surprise in a subject which has been worked at rather piecemeal, the interest of one investigator being centred in such a ubiquitous and commonplace phenomenon as geotropism, while the interest of another lies in the significance of biomagnetism for space travel, and so on. But it should surely have been possible, starting from scratch, to have produced a work which was a more coherent and satisfactory introduction to such an interesting bypath (for that is all it is at the moment) of modern investigation than has been done. As it is, most of the articles appear to be restricted accounts of special pieces of work rather than essays, complete in themselves, designed to introduce newcomers into interesting aspects of the broader subject. Perhaps the editor was set the task of attaining two mutually irreconcilable objectives; but it scarcely seems unfair to say that neither has been satisfactorily achieved. This is a pity, for a 'background introduction' and a summary of present-day knowledge and research activity could both have been very useful.

These criticisms do not mean, however, that the book is of little value. To initiated or half-initiated workers it will probably prove very valuable and serve to broaden their horizons. It is rather its lack of any coherent emphasis, treatment and standpoint which is cause for regret, not its failure to include good and interesting material. But that is a common criticism of modern symposia, and no doubt one very difficult to remedy.

On particular articles the following comments may be made from the point of view of a biologist. There is a reasonably adequate introduction to the subject of magnetic fields, and of their possible modes of interaction with biological units, though some clear diagrams would have been a great advantage. The discussion of the characterization of magnetic fields in mathematical terms leaves rather a lot to be desired; it would surely have been better to have made magnetic moment the basis of magnetic definitions rather than pole strength. In this introductory section it would have been a great help had there been a clear résumé of methods of measuring magnetic fields, a requirement which most workers will some time have to meet and about which they may well start off quite ignorant.

The second and third sections, dealing with the effects of strong magnetic fields, contain accounts of interesting but specialized work, such as haematological changes in mice, wound-healing and tissue regeneration in animals, magnetotropism in plants, tissue respiration, increase of bacterial growth and increase of trypsin activity. These articles make it fairly plain that the subject is as yet only in its infancy.

The fourth section, dealing with the effects of very weak magnetic fields, is probably the most interesting of all. The orientational responses of planarians and snails, the reflexes of the water-diviner and the navigational mechanism of birds are lines of investigation that suggest exciting possibilities. Further, the magnetic fields involved might be described as natural ones, and this gives them an added significance.

This is a book which workers in this field will undoubtedly wish to possess. The format leaves something to be desired, and so does the attempt to provide a unified and adequate approach to the topic of biomagnetism; nevertheless it contains much of interest and value.

D. C. SPANNER

## METAL CHELATES

### Chelating Agents and Metal Chelates

Edited by F. P. Dwyer and D. P. Mellor. Pp. xv + 530. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1964.) 121s. 6d.

THE publication of *Chelating Agents and Metal Chelates* is overshadowed by the tragic death of one of the authors—Francis P. J. Dwyer. As the inspiration

for its preparation derived mainly from him, the book provides a worthy monument to his memory. The purpose of the book is a good one, and so, in the main, is the execution of this purpose.

The book is a composite work and as a result there is some lack of co-ordination between the different parts but, on the whole, its coverage is satisfactory. It begins with a useful introductory article on "Historical Background and Fundamental Concepts" by D. P. Mellor, followed by a dissertation on the "Nature of the Metal-ligand Bond" by D. P. Craig and R. S. Nyholm. The latter chapter suffers from the lack of an adequate discussion of the ligand field theory. Such discussion seems desirable in view of the frequency with which this theory is referred to in some of the later chapters, particularly that on oxidation-reduction potentials. The introductory chapters are followed by chapters on "Bidentate Ligands" by O. M. Harris and S. E. Livingstone, and "Design and Stereochemistry of Multidentate Ligands" by H. A. Goodwin. The "Metal Chelates of Ethylene-diaminetetraacetic Acid and Related Substances" are the subject of a separate chapter by F. L. Garvan. These chapters contain much useful information on structure and stability of complexes. In a future edition it would be desirable to include a short section on the practical uses of chelating agents in analysis and sequestration.

A chapter on "Optical Phenomena in Metal Chelates", by A. M. Sargeson, describes methods of resolution of optical isomers and brings out the value of conformational analysis and measurement of optical rotatory dispersion in the determination of their structure. Sargeson also co-operates with D. A. Buckingham in an interesting discussion of the factors which determine the oxidation reduction potential of metal complexes. This is a field of considerable importance to those with biological interests and it is unfortunate that the sign convention used here is the opposite of that with which they are familiar. It is a sad commentary on the inability of chemists to agree, that two different sign conventions should be used in different parts of the same book. This appears to confuse even the authors, for on p. 255 the text and Fig. 2 disagree in respect of sign. There is other evidence of carelessness about signs (for example, in Table 4, Chapter 1, and Table 4, Chapter 6) which may confuse some of the students and many of the biologists at whom the book is aimed.

The later chapters dealing with subjects of biological interest are a little disappointing. In the preface, it is stated that the book is primarily intended as a work of reference for senior students and research workers. In this respect it should be very successful. The hope is also expressed that the book will interest biologists and medical scientists and this is less certain of fulfilment. The attempt to bridge the gap between those with biological interests and the co-ordination chemists is laudable, for metals are of great importance in biological processes and our understanding of these processes is often limited by our ignorance of the chemistry of metal complexes. The book does indeed provide a useful basis for further consideration of the biochemical functions of metals, but biologists and biochemists interested in this field will wish that the subject had been developed more effectively in this direction. Dwyer's chapter on "Enzyme-Metal Ion Activation and Catalytic Phenomena with Metal Complexes" deals very scantily with the role of metals in enzyme catalysis, a subject which has for some time been ripe for consideration by experts on the properties of metal complexes. The chapter on "Metal Chelates in Biological Systems", by Dwyer and Shulman, is largely devoted to pharmacological and bacteriostatic effects of synthetic chelates, a field of interest in itself, but one where our knowledge is too empirical to offer much scope for the inorganic chemist except in preparation of suitable chelates. The final chapter on "Physical and Co-ordination Chemistry of the Tetrapyrrole Pigments", by J. E. Falk and J. N. Phillips, provides a good summary of this topic, but again is rather

deficient in its treatment of the naturally occurring complexes—the haemoproteins, chlorophyll and vitamin B<sub>12</sub> and its derivatives.

When the time comes to prepare a new edition it is hoped that more attention will be directed to these natural chelates. In the meantime, those concerned with the writing of the book are to be congratulated on the production of a work that is well worth possessing.

G. LEAF

## A COURSE IN STATISTICAL MECHANICS

### Equilibrium Statistical Mechanics

By Prof. Frank C. Andrews. Pp. xii+206. (New York and London: John Wiley and Sons, Inc., 1964.) 38s.

### Statistical Mechanics and Dynamics

By H. Eyring, D. Henderson, B. Jones Stover and E. M. Eyring. Pp. xiii+508. (London, New York and Sydney, John Wiley and Sons, Ltd., 1964.) 113s.

### Ergodic Theory In Statistical Mechanics

By I. E. Farquhar. (Monographs in Statistical Physics and Thermodynamics, Vol. 7.) Pp. viii+235. (London and New York: Interscience Publishers, a Division of John Wiley and Sons, Ltd., 1964.) 90s.

ONE of the main aims of statistical mechanics is to obtain a more perspicuous insight into the macroscopic behaviour of matter from a knowledge of some of its microscopic properties. Conversely, we are also often able to extend our understanding of its microscopic behaviour by means of judicious comparisons between theory and experiment on the macroscopic scale. From the educational point of view, it is therefore of considerable importance to the professional scientist in many fields. Unfortunately, as Andrews points out in his preface to *Equilibrium Statistical Mechanics*, all too often there is little time in the busy undergraduate curriculum for a unified treatment of the subject, although incursions are frequently made into it from other related disciplines. In this connexion, the three books under review, although published independently, can be regarded as a course in statistical mechanics, of gradually increasing depth and scope of treatment. At a comparatively elementary level, Andrews has set himself the task of providing an introductory account of the basic theory, illustrated by a number of the more important applications, while maintaining a high degree of mathematical simplicity. On the other hand, Eyring *et al.* in *Statistical Mechanics and Dynamics* have produced a much more detailed treatment embracing a wide range of applications, including, for example, such topics as chemical kinetics. *Ergodic Theory in Statistical Mechanics*, by Farquhar, is obviously for the specialist who is interested in a more formal approach to the fundamental ideas of statistical mechanics.

Andrews approaches the problem of developing a logical introduction to the subject by first discussing the elements of probability theory, leading to the concept of the ensemble average. It is commendable that the micro-canonical, canonical and grand canonical ensembles are mentioned at an appropriately early stage in the book, although most of the treatment is in terms of the canonical ensemble. The probability distributions corresponding to the various ensembles are defined and their significance explained in a straightforward manner without recourse to the all too familiar device, involving the rather indiscriminate use of Stirling's theorem and Lagrange's undetermined multipliers, that is so often characteristic of books at this level, in which it is rarely explained with sufficient care to be meaningful (with notable exceptions, of course). Andrews then establishes a link between entropy and probability through the ensemble average

of the energy; the discussion here, although adequate, could profitably have been expanded. He then goes on, in roughly the remaining two-thirds of the book, to a number of illustrative applications, including ideal classical and quantal gases, dense gases and fluctuations. In particular, the relationship between fluctuations and the mechanical view of thermodynamics is explained in order to complete the outline picture of the subject.

While this outline represents quite a satisfactory achievement of the original limited aims, it inevitably lacks completeness in comparison with the more extensive treatment afforded by Eyring's book, to which it would nevertheless form a helpful introduction. Eyring has set a much higher target: that of describing the main basic techniques and including all the applications one could hope to see mentioned in a single volume. We are presented with three methods of approach to the fundamental theory: the technique of compounding a known and an unknown system, the classical approach of Gibbs and the Darwin-Fowler method of steepest descents, with supporting chapters on classical mechanics, thermodynamics and quantum theory, which comprise admirable summaries, in their own right, of their respective contributions to the main theme. It is indeed a luxury to have all this information so neatly assembled. Furthermore, the list of applications is impressive, ranging through specific heats, radiation, electric and magnetic properties, etc., to surface chemistry, with a concluding chapter on relaxation times. Although the treatment of each individual topic is necessarily somewhat compressed, it is still very complete and taken to quite an advanced standard, with many references. It is this completeness which enhances the value of the book, since it extends also to considerations of reaction rates, thus emphasizing, in accordance with the title, the dynamic nature of all physical processes, including equilibrium and the approach to equilibrium. From this point of view, the book is highly to be recommended.

While Eyring tends to regard statistical mechanics as better to be justified *a posteriori*, he does give a short, clear account of the difficulties associated with the ergodic and quasi-ergodic hypotheses. On the other hand, Farquhar quite definitely regards the purely pragmatical view of statistical mechanics as reducing it to the status of an *ad hoc* technique unrelated to the rest of physics. Ergodic theory is concerned with just this problem of examining the precise circumstances in which it is possible to pass from a dynamical to a thermodynamical description of a macroscopic system.

Farquhar's book is the seventh volume of a series of monographs in statistical physics and thermodynamics. It is divided into three sections, dealing in turn with the general principles of the theory and their subsequent application in both classical and quantal statistics. The approach is intended for the physicist rather than the mathematician, and includes an outline of any necessary mathematics, such as Lebesgue measure, as part of the treatment. It is limited also to a consideration of ergodic theory within classical and quantal statistics, and it does not deal with the approach of a system to equilibrium; these restrictions being in accordance with the aims of the series of which the book forms a part. Nevertheless, it constitutes a unique and lucid survey of the problem, as it relates to statistical mechanics, without in any way disguising the various points that still await elucidation. The usefulness of this kind of exercise lies particularly in the stimulation it provides towards a more critical appraisal of the foundations of the subject.

Of these three books, it is more than likely that Eyring's will be found to be the most generally useful, as a recent and most welcome addition to what are usually regarded as the standard texts for the serious student. This judgement does not detract from the contributions made by the works of Andrews and Farquhar in their respective spheres—the latter, especially, warranting the careful attention of the specialist.

F. J. PHARSON

### Bessel Functions

By Andrew Young and Alan Kirk. Part 4: Kelvin Functions. (Royal Society Mathematical Tables, Vol. 10.) Pp. xxvii+97. (Cambridge: At the University Press, 1964. Published for the Royal Society.) 60s. net.

THIS volume continues the series of tables of Bessel functions issued by the Mathematical Tables Committee of the Royal Society and its predecessor, a similar committee of the British Association for the Advancement of Science. The functions tabulated are the real and imaginary parts, and the modulus and phase, of the Bessel functions  $i^n I_n(xe^{i\pi/4})$  and  $i^{-n} K_n(xe^{i\pi/4})$  for real  $x$  and  $n$ . These occur in the solution of the diffusion equation in cylindrical co-ordinates, in the description of eddy currents in cylindrical conductors due to fluctuating magnetic fields, and other problems.

In a mathematical introduction, formulae relating to these functions are listed, the calculation of the tables is described, and a bibliography is provided. In the main tables, the functions are tabulated for  $n = 0(1)10$  and  $x = 0(0.1)10$  to 7 figures, with differences given as aids to interpolation. Basic 15-figure tables for the functions of order 0 and 1 are also given and are believed to be free of errors. There are also 8-figure tables for  $n = 0, 1, 2$  and  $x = 0(0.01)2.5$ , and auxiliary tables for the functions  $i^n x^n I_n(xe^{i\pi/4})$  and  $i^{-n} x^n K_n(xe^{i\pi/4})$ .

The arrangement and printing of these tables are excellent.

A. ERDÉLYI

### Non-Metallic Inclusions In Steel

By Roland Kießling and Nils Lange. Pp. 104. (London: The Iron and Steel Institute, 1964.) 42s.

ALL commercial steels contain non-metallic inclusions which often have important effects on the properties of the steels. Thus, from the earliest days of metallography, these inclusions have been extensively investigated, Swedish metallurgists playing a prominent part in such investigations. The most recent report by Prof. R. Kießling and Mr. N. Lange, of the Swedish Institute for Metal Research, is a fine example of Swedish research.

The investigation of inclusions has been revolutionized by the development of the technique of electron-probe analysis, which enables a quantitative analysis of the inclusions to be carried out *in situ*. The use of this technique, together with optical microscopy of the highest standard, has produced a report on inclusions which will be a standard text for all metallographers who are interested in ferrous alloys.

The authors state that a great many inclusions in steel belong to the system  $\text{MnO-SiO}_2\text{-Al}_2\text{O}_3$ , and the presentation in the report has been based on this system, but inclusions of the general formula:

and a discussion of the different iron oxides are also included. The report consists of a discussion of the various phases present in these systems illustrated by photomicrographs of hybrid inclusions. Each photomicrograph is accompanied by details of the type of steels, its analysis, the electron probe analysis of the various phases in the inclusion and comments. There are also useful introductory remarks and comments through the text.

J. H. RENDALL

### Galvanomagnetic Effects In Semiconductors

By Albert C. Beer. (Supplement 4 to Solid State Physics: Advances in Research and Applications.) Pp. xiv+418. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1963.) 96s. 6d.

THE importance of measurements of the Hall effect and electrical conductivity in determining the carrier concentration and mobility in a simple extrinsic semiconductor is universally recognized. However, the simple

band model and scattering mechanisms that were widely accepted fifteen years ago are now known to be only rarely a good approximation. It is in the more complex realistic situations that the more detailed investigations of the galvanomagnetic effects become particularly fruitful. For example, measurements of the various Hall and magneto-resistance coefficients at low magnetic fields have been used in determining the effective mass tensors in the multi-valley energy bands of several materials. Such measurements are particularly useful when the carrier mobility, even at low temperatures, is too small to allow cyclotron resonance and similar effects to be exploited. The extension of the measurements to high magnetic fields is especially useful for mixed or intrinsic semi-conductors.

Dr. A. C. Beer's book gives a really comprehensive treatment of the galvanomagnetic effects, starting from the simplest extrinsic model and progressing, for example, to multiple bands, non-quadratic energy surfaces and complex scattering processes. It is not a practical book in the sense that it does not describe techniques, but it is nevertheless most suitable for experimentalists since it sets out the theory in an exceptionally plain and straightforward manner. It is a pity that so little attention is paid by Dr. Beer to the thermomagnetic effects, since they can often be measured easily at the same time as the galvanomagnetic effects and they provide useful additional information; they are, moreover, finding practical application in low-temperature energy converters. However, having restricted himself to the galvanomagnetic phenomena, which are, of course, themselves utilized in devices ranging from magnetometers to amplifiers, Dr. Beer has produced an excellent text, well up to the highest standards of the series of which this book forms part. H. J. GOLDSMID

### The Natural Philosopher

Vol. 3. Edited by Daniel E. Garshenson and Daniel A. Greenberg, in association with Dennis Flynn. (A Series of Volumes containing Papers devoted to the History of Physics and the Influence of Physics on Human Thought and Affairs through the Ages.) Pp. 111. (New York and London: Blaisdell Publishing Company, a Division of Ginn and Company, 1964.) 15s.

THIS little manual deals, in four chapters, with a variety of themes of interest in the history and evolution of physics. Its particular merit is that the subjects selected are off the beaten track, and illuminate some unusual recesses of the mind. The first contribution sets Einstein well in the centre of the stage during the period of the wave-particle discussion. We see an aspect of quantum mechanics too often over-simplified, namely the properties of radiation and gases, with special reference to the Bose statistics. This happened in 1924 when Planck's radiation law was derived, not from classical electromagnetic theory as hitherto, but directly from light quanta; in the event, the prelude to Schrödinger's work.

The next paper deals with that somewhat obscure Swiss mathematician Le Sage (1724-1803), who evolved an ingenious theory of gravitation of a strictly mechanical kind, comprising his 'ultramundane corpuscles'. At the time there was no experimental evidence in support of such a system, but about a hundred years later the matter was taken up again, only to be proved untenable by Clerk Maxwell and Poincaré.

Next comes a useful table of references to Faraday's papers on electricity, with explanations and notes.

Finally, the reader is given a very clear account of the Eleatic School of Greek philosophy, and its impact on physics. In effect, this was the fundamental role of logic, even if it contradicted experience. Time was to correct this, without destroying the quest for vigour. We also owe to this school the beginnings of metaphysics, in the recognition of various levels of being, an accomplishment essentially due to Parmenides. F. I. G. RAWLINS

## THE NATURAL ENVIRONMENT RESEARCH COUNCIL

By SIR GRAHAM SUTTON, C.B.E., F.R.S.

Chairman

THE Natural Environment Research Council came into being legally on June 1, 1965. Its formation was the outcome of a long process of consideration. Such a Research Council was first envisaged by the Slater Committee, constituted by the Advisory Council for Scientific Policy, and later, in a somewhat different form, by the Committee on the Organization of Civil Science under Sir Burke Trend. The statutory authority for the creation of the Natural Environment Research Council is contained in the Science and Technology Act, which received the Royal Assent at the end of March 1965.

The new Council is one of four for which the Secretary of State for Education and Science is responsible, the others being the old-established Medical and Agricultural Research Councils and the newly formed Science Research Council. In broad terms, the Natural Environment Research Council is concerned with those sciences, both physical and biological, that relate to man's natural environment. Specifically, to quote its Royal Charter, it is established "to encourage and support research by any person or body in the Earth sciences and ecology and in particular (but without prejudice to the foregoing) in geology, meteorology, seismology, geomagnetism, hydrology, oceanography, forestry, nature conservation, fisheries or marine and freshwater biology". In addition to carrying out research in these subjects by direct control of certain governmental establishments and by support for others, it is also authorized to make grants for post-graduate instruction.

The Council is thus a 'federal' organization, with a number of 'component bodies', that also provides support for certain independent institutions, for example, in marine and freshwater biology. The component bodies, which are directly controlled by the Council, in the past have been within various governmental departments or else had a separate Charter. They are: the Nature Conservancy, the Home and Overseas Geological Surveys (including the Geological Museums), the National Institute of Oceanography and the Hydrology Research Unit. The Council has also taken over the Development Commission's responsibilities for fisheries research as well as policy direction and financial support for research in geophysics (geomagnetism and seismology) carried out at the Observatories of the Meteorological Office. It will also be associated with the general programme of research of the Meteorological Office and, in consultation with the Forestry Commission, will support long-term forestry research in the universities.

The Royal Charter of the Natural Environment Research Council lays down that the Council shall consist of a chairman and not more than fifteen and not less than ten members. The Secretary of State for Education and Science, with the advice of the Royal Society and interested governmental departments, has appointed the following for the initial phase: Sir Graham Sutton (chairman), Lord Howick, Mr. F. C. Bawden, Sir Edward Bullard, Prof. A. R. Clapham, Prof. F. K. Hare, Prof. J. E. Harris, Prof. M. V. Laurie, Prof. M. J. Lighthill, Prof. O. J. Mitcheson, Mr. N. A. F. Rowntree, Prof. S. K. Runcorn, Prof. J. H. Taylor, Prof. V. O. Wynne-Edwards and Dr. O. M. Yonge. The secretary of the Council, who is also its accounting officer, is Mr. R. J. H. Beverton, formerly deputy director of the Ministry of Agriculture, Fisheries and Food's Fisheries Laboratory at Lowestoft. The Headquarters are at State House, High Holborn, London, W.C.1.

At its first meeting on June 30, 1965, the Council set up a number of standing committees. The Charter stipulates that one committee shall be the Nature Conservancy with its present membership. The chairman of this committee is Lord Howick. The other committees are: the Geology and Geophysics Committee (chairman, Prof. Mitcheson), the Oceanography and Fisheries Committee (chairman, Prof. Lighthill, with Prof. Harris as deputy chairman) and the Hydrology Committee (chairman, Mr. Rowntree). The committees, in addition to supervising the work of their respective component bodies, will also be responsible to the Council for recommending research grants, training awards and fellowships in their fields.

The interests of the new Council are thus large and diverse, embracing both physics and biology. The degree of control, however, varies over the field of natural environmental science. The main effort in meteorological research in the United Kingdom comes from the Meteorological Office, which will remain with the Ministry of Defence, as recommended by the Trend Committee. However, as meteorology by its very nature must enter into many parts of environmental science (particularly in hydrology, nature conservation and oceanography) it is clear that the association between the Natural Environment Research Council and the research work of the Meteorological Office must be close. Some aspects of meteorological research, for example those relating to professional activities such as weather forecasting, will continue to be the exclusive concern of the Meteorological Research Committee, but in others, notably climatology and rainfall studies, it will be essential to set up close links. In geophysics there are some difficulties arising as a heritage of the past. Routine measurements of the Earth's magnetic field are made at the Eskdalemuir and Lerwick Observatories of the Meteorological Office and at Hartland Point, which comes under the Royal Greenwich Observatory and is therefore with the Science Research Council. Regular seismological observations will continue at Eskdalemuir under the Meteorological Office, but the programme of research in both these disciplines will be directed by the Natural Environment Research Council. There is a certain amount of administrative untidiness in these arrangements, but this is not expected to have any serious consequences for the research programmes. In other fields the Council should be able to exercise a much-needed integrating function. The formation of one committee to deal with physical oceanography, marine biology and fisheries should be valuable for the development of marine science, and the combination of geology and geophysics, with the amalgamated Home and Overseas Geological Surveys as the component body, illustrates the desire for close union of service and academic interests in this field. In hydrology, there is a clear need for pioneering work to establish a programme of scientific work designed to help the users of water.

The Council recognizes that one of its most important functions will be to provide funds for university research and grants and training awards in the disciplines that come under its control. Hitherto, the administration of this programme was with the Department of Scientific and Industrial Research. Many of the permanent staff that dealt with these matters are now with the Science Research Council; others will be transferred to the Natural Environment Research Council. It is essential that the change-over be as smooth as possible, and it is

a fortunate circumstance that it has proved possible to accommodate the headquarters of both Councils in the same building. For the time being, the machinery of administration will be much the same as hitherto, with the Natural Environment Research Council taking over

responsibility for the parts of the grants and awards programme that lie within its field. The emphasis on continuity should be particularly welcomed by universities and others concerned with this important aspect of the Government's policy for science.

## A PHYSICAL BASIS FOR LIFE DETECTION EXPERIMENTS

By Dr. J. E. LOVELOCK

Bowerchalke, Nr. Salisbury, Wiltshire

THE design of an efficient and unequivocal experiment in extra-terrestrial life detection should take into account: (1) A definition of life stated in terms favourable for its recognition. (2) A description of the past and present environment of the planet to be sampled.

As yet, there is no formal physical statement to describe life from which an exclusive definition for experimental purposes could be drawn. Moreover no comprehensive description is available of the atmospheric as well as the surface physical and chemical environment of any of the planetary bodies.

It is not surprising, in view of the vast expense of space-probe experiments and of the formidable uncertainties already stated here, that the proposed experiments in life detection all ask the cautious geocentric question: "Is there life as we know it?" Most certainly it is difficult to envisage in detail an alien biochemistry; it would seem pointless and very uneconomic to send a space probe to detect a speculative life-form.

It is the object of this article to show that we are not necessarily limited to experiments based on the recognition of a specific life-form, either Earth-like or alien. Also, that it is possible, by accepting a limited phenomenological definition of life, to design simple experiments from the general recognition of life phenomena, including that with which we are familiar. The application of this approach to experiments in life detection is the basis of the discussion which follows.

### Recognition of Life

It is a relatively simple matter to distinguish between living and inorganic matter on Earth by biochemical experiments even though no formal definition of life in biochemical terms exists. Experience suggests, for example, that a system capable of converting water, atmospheric nitrogen and carbon dioxide into protein, using light as a source of energy, is unlikely to be inorganic. This approach for recognition of life by phenomenology is the basis of the experiments in detection of life so far proposed. Its weakness lies not in the lack of a formal definition but in the assumption that all life has a common biochemical ancestry.

It is also possible to distinguish living from inorganic matter by physical experiments. For example, an examination of the motion of a salmon swimming upstream suggests a degree of purpose inconsistent with a random inorganic process. The physical approach to recognition of life is no more rigorous, at this stage, than is the biochemical one; it is, however, universal in application and not subject to the local constraints which may have set the biochemical pattern of life on Earth.

Past discussions of the physical basis of life<sup>1-3</sup> reach an agreed classification as follows: "Life is one member of the class of phenomena which are open or continuous reaction systems able to decrease their entropy at the expense of substances or energy taken in from the environment and subsequently rejected in a degraded form". This classification is broad and includes also phenomena such as flames, vortex motion and many others. Life

differs from the other phenomena so classified in its singularity, persistence, and in the size of the entropy decrease associated with it. Vortices appear spontaneously but soon vanish; the entropy decrease associated with the formation of a vortex is small compared with energy flux. Life does not easily form, but persists indefinitely and vastly modifies its environment. The spontaneous generation of life, according to recent calculations from quantum mechanics<sup>4,5</sup>, is extremely improbable. This is relevant to the present discussion through the implication that wherever life exists its biochemical form will be strongly determined by the initiating event. This in turn could vary with the planetary environment at the time of initiation.

On the basis of the physical phenomenology already mentioned, a planet bearing life is distinguishable from a sterile one as follows: (1) The omnipresence of intense orderliness and of structures and of events utterly improbable on a basis of thermodynamic equilibrium. (2) Extreme departures from an inorganic steady-state equilibrium of chemical potential.

This orderliness and chemical disequilibrium would to a diminished but still recognizable extent be expected to penetrate into the planetary surface and its past history as fossils and as rocks of biological origin.

### Experiments for Detection of Life

The distinguishing features of a life-bearing planet, described here, suggest the following simple experiments in detection of life:

(A) *Search for order.* (1) Order in chemical structures and sequences of structure. A simple gas chromatograph or a combined gas chromatograph-mass spectrometer instrument would seek ordered molecular sequences as well as chemical identities.

(2) Order in molecular weight distributions. Polymers of biological origin have sharply defined molecular weights, polymers of inorganic origin do not. A simple apparatus to seek ordered molecular weight distributions in soil has not yet been proposed but seems worthy of consideration.

(3) Looking and listening for order. A simple microphone is already proposed for other (meteorological) purposes on future planetary probes; this could also listen for ordered sequences of sound the presence of which would be strongly indicative of life. At the present stage of technical development a visual search is probably too complex; it is nevertheless the most rapid and effective method of life recognition in terms of orderliness outside the bounds of random assembly.

(B) *Search for non-equilibrium.* (1) Chemical disequilibrium sought by a differential thermal analysis (DTA) apparatus. Two equal samples of the planetary surface would be heated in a DTA apparatus: one sample in the atmosphere of the planet, the other in an inert gas, such as argon. An exotherm on the differential signal between the two samples would indicate a reaction between the surface and its atmosphere, a condition most unlikely to be encountered where there is chemical equilibrium as in the absence of life. It should be noted

that this method would recognize reoxidizing life on a planet with a reducing atmosphere. This experiment could with advantage and economy be combined with, for example, the gas chromatography mass spectrometry experiment (A1) where it is necessary to heat the sample for vaporization and pyrolysis.

(2) Atmospheric analysis. Search for the presence of compounds in the planet's atmosphere which are incompatible on a long-term basis. For example, oxygen and hydrocarbons co-exist in the Earth's atmosphere.

(3) Physical non-equilibrium. A simplified visual search apparatus programmed to recognize objects in non-random motion. A more complex assembly could recognize objects in metastable equilibrium with the gravitational field of the planet. Much of the plant life on Earth falls into this category.

Experiments A1, B1 and B2 are the most promising for the development of practical instruments. Indeed, the gas chromatography-mass spectrometry combination experiment and the DTA experiment already proposed for planetary probes<sup>7</sup> are, with minor modifications, capable of recognizing the ordered sequences and chemical disequilibrium discussed earlier. Experiment B2, atmospheric analysis, is simple and practical as well as important in the general problem of detection of life. A detailed and accurate knowledge of the composition of the planetary atmosphere can directly indicate the presence of life in terms of chemical disequilibrium; such knowledge also is complementary to the understanding of other life detection experiments and to the planning of subsequent experiments. Even on Earth where life is abundant there are many regions, such as those covered by fresh snow, where a surface sample might be unrewarding in the search for life. The atmospheric composition is largely independent of the site of sampling and provides an averaged value representative of the steady state of chemical potential for the whole planetary surface.

Fig. 1 shows the abundance of hydrocarbons of carbon number between 11 and 33 for abiogenic hydrocarbons of the Fischer-Tropsch process<sup>8</sup> and hydrocarbons of biological

origin, wool wax<sup>9</sup>. Poisson distributions around the predominant hydrocarbon numbers are shown as solid lines. The inorganic hydrocarbons fit closely the expected Poisson distribution for a state of chemical equilibrium. By contrast the biological hydrocarbons show large departures in the distribution of their abundance from this equilibrium state; also, especially for the higher molecular weight alkanes, a two-carbon ordered sequence is well established.

In a similar manner with experiment B1 the disequilibrium associated with life can be demonstrated. A few mg of soil heated in a DTA apparatus in air shows a large exotherm when compared with a similar reference sample heated in argon. The combustion of even a few micrograms of organic matter in these circumstances is capable of generating a detectable signal.

### Detection of Life on Mars

Ordinarily one does not look for fish in a desert, nor for cacti on an ice cap. Should we, therefore, look for microorganisms of Earth-like habits on Mars, or should we rather ask one or more of the general questions discussed here? The answer to this must depend on the history of Mars, past and present.

The following is the only sure information so far available on Mars. It is dry. The atmosphere is thin and contains no more than a trace of oxygen. The flux of solar radiation at the surface, although less than on Earth, is also less filtered and may include an appreciable content of energetic radiation; in particular, short wave-length ultra-violet. The temperature range includes periods above zero centigrade. Finally, but less certain, is the possibility<sup>4</sup> that oxides of nitrogen are present in appreciable amounts.

If these conditions are representative of Mars in the past as well as now, there seems no reason to assume that life, if present at all, can resemble that on Earth. However, it is possible that Mars was once Earth-like (primeval non-living Earth) and has changed physically to its present state; or less likely that the present state of Mars, like that of the Earth, is a consequence of biological change. For success a geocentric biochemical experiment must assume that Mars was once Earth-like and that life is still surviving in a highly adapted form yet still recognizable to the experiment.

If Mars is as it always was or has been changed to its present state by biological action, then life, if there now, would be very different from that we know. Could we conceive of living systems in liquid  $N_2O_4$  as an ionizing solvent? Could they use hard ultra-violet as a source of energy? Is cellular life necessary in a dry environment, or did cell membranes evolve on Earth to offset the overwhelming effects of dilution in the primeval seas? What sort of Martian biochemistry could have generated the present atmosphere?

Answers to these questions are important in the design of experiments to detect particular life-forms; thus, with a growth experiment, or a biochemical experiment, the strength, composition and conditions of incubation of the medium are of vital importance. This information, however, is not needed in the general detection of life. In view of what is not known of conditions on Mars, the physicochemical experiments in life recognition such as experiments A1 and B1 and B2 seem more worth considering for early probe experiments. These simple experiments do not require a prior knowledge of the planetary environment and are not limited to Earth biochemistry.

I thank A. Zlatkis and P. G. Simmonds of the University of Houston for their advice and for conducting and providing me with the results of the differential thermal analysis experiments suggested in the discussions here. I also thank G. Hobby and G. Mamiknian of the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, for their advice.

Fig. 1. The abundance of *n*-alkanes from an inorganic source (A), Fischer-Tropsch hydrocarbons, and from a biological source (B), wool wax. The observed abundances (●—●) are compared with normalised Poisson distributions (—) around the predominant alkanes.

## BIRTH-DEATH AND OTHER MODELS FOR MICROBIAL INFECTION

By PROF. PETER ARMITAGE

Department of Statistics, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1

DR. G. G. MEYNELL

Guinness-Lister Research Unit, Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W.1

AND

DR. TREVOR WILLIAMS

Department of Mathematics, Duke University, Durham, North Carolina

SHORTLEY and Wilkins<sup>1</sup> have recently analysed certain experimental data derived from microbial infections. They first consider the relation observed between size of dose and the proportion of hosts responding, and draw a conclusion of considerable biological interest, namely, that host resistance is often discontinuously distributed, with the hosts falling into two homogeneous groups. In our opinion these authors lay undue stress on the two-group distribution, which we believe to be supported by very few sets of data. Secondly, Shortley and Wilkins find strong evidence in favour of a simple birth-death model of infection. Our examination of this type of model shows that although its predictions, qualitatively considered, are in remarkable agreement with the data, a detailed analysis encounters serious difficulties.

In most experimental infections a given host is unlikely to respond to inoculation of a single organism, and this finding has been accounted for by two main types of model, originally distinguished by Halvorson<sup>2</sup> in 1935. The first is derived from the pharmacological work of Trevan<sup>3</sup> and postulates an individual effective dose (IED) for each host such that it will certainly respond to a dose equalling or exceeding its IED; the hypothesis is, therefore, deterministic in nature. Inoculated organisms can be thought of as co-operating to 'saturate' the host defences. In the alternative class of model, however, inoculated organisms are assumed not to co-operate but to act independently—hence the designation 'hypothesis of independent action'<sup>4</sup>—and each organism is assumed to have an independent probability,  $p$ , of multiplying sufficiently to produce a response: all hypotheses based on this assumption are, therefore, stochastic. Whenever inoculation of one organism is not invariably followed by a response, the value of  $p$  is clearly less than unity ( $<1$ ). The reasons suggested for this serve to subdivide stochastic hypotheses:

(1) The culture from which inocula are drawn might consist of a mixture of completely virulent and completely avirulent organisms (for which  $p=1$  and 0, respectively) so that the value of  $p$  is the proportion of virulent organisms in the culture. This is unlikely in most systems<sup>5</sup>.

(2) All the organisms in the culture might be fully virulent but each of the sites they reach after inoculation might be either completely favourable or completely lethal to them. This only seems likely when inocula are applied to the external surface of the host, as by ingestion<sup>6</sup> or inhalation<sup>7</sup>, when  $p$  is the probability per inoculated organism of reaching the interior. Both these possibilities presuppose that the outcome is decided once the organisms reach their final sites of deposition, presumably within a short time of inoculation.

(3) In contrast, the birth-death model assumes that the outcome is determined by successive random events which continually operate as long as even one organism remains viable in its host. Thus, in each small interval of time  $dt$  after inoculation, each organism still extant has a probability  $\lambda dt$  of dividing, a probability  $\mu dt$  of dying, and a probability  $1 - (\lambda + \mu)dt$  of doing neither. When  $\mu > \lambda$ , the host must invariably survive if the dose is substantially less than the final number of organisms causing the response ( $C$  in ref. 8), because each clone (that is, each inoculated organism and its progeny) will be extinguished before it can increase to any extent. The model therefore postulates  $\lambda > \mu$  with  $p = 1 - (\mu/\lambda)$  for infections leading to a response. The increasing probability of response with increase in size of dose can here be thought of as reflecting the chance that one or more clones will be 'lucky' enough to increase to  $C$ . Processes of this sort are considered in many branches of science<sup>9</sup> and some of the underlying mathematical arguments are far from novel. For example, equation 14 in Shortley and Wilkins<sup>1</sup>,  $ED_{50} = 0.69 / \{1 - (\mu/\lambda)\}$ , follows immediately from the probability of extinction in a birth-death process derived by Bartlett in 1946 (ref. 10).

Many attempts have been made to establish the model that best describes microbial infection. The deterministic hypothesis of the IED has been objected to<sup>4,11</sup>, because, in systems where the  $ED_{50}$  is relatively small (for example, 10<sup>3</sup>), it has always been hard to see how such a dose could 'saturate' the host. However, viable counts show that, whatever the outcome of inoculation, the number of organisms per host usually increases exponentially at first<sup>12,13</sup>, perhaps for several days, and that only afterwards do the counts on non-responders decline while those for responders continue to rise to  $C$ . Consequently it could be argued that the number of organisms determining the outcome is not that inoculated but the larger number present when the growth curves for responders and non-responders diverge. It may be noted, incidentally, that growth curves on responders certainly do not appear to originate from a proportion  $p$  of the dose, as might occur if infection complied with possibilities 1 or 2 already described here. On the contrary, many growth curves rise from the whole dose, whatever the outcome and whatever the value of  $p$ <sup>12,13</sup>.

Birth-death models are very attractive, since they have far greater predictive power than deterministic models. Given the values of  $p$  and  $C$ , and assuming that the hosts do not differ in resistance, the basic birth-death model developed by Williams<sup>14</sup> predicts many quantitative features of an infection, of which those marked by asterisks below also follow from possibilities 1 and 2. They include

*In response to the need . . .*

for a periodical which presents the results of investigations of mechanism of drug action or of toxicity at the molecular level . . . ACADEMIC PRESS is proud to announce the publication of a new journal . . .

## MOLECULAR PHARMACOLOGY

An International Journal

Edited by Avram Goldstein

Published under the auspices of the American Society for Pharmacology and Experimental Therapeutics, Inc.

Included are articles which describe applications of the methods of biochemistry, biophysics, genetics, and molecular biology to pharmacologic or toxicologic problems . . . as well as fundamental investigations which, although not concerned with drugs, nevertheless provide an immediate basis for further study of the molecular mechanism of drug action.

Specific areas of interest include:

- Stereo-chemical, electronic, and other parameters of drug architecture
- Conformation analysis of receptors and their function
- Drug-enzyme and other interactions between drugs and macromolecules
- Drug effects upon gene replication and transcription, and on protein synthesis
- Mechanism of action of antibiotics and other growth-inhibitory drugs
- Drug-induced changes in macromolecular structure, allosteric transitions
- Drug-induced alterations in metabolic pathways
- Effects of hormones and other drugs on cellular regulatory mechanisms
- Chemical mutagenesis, carcinogenesis, and teratogenesis
- Pharmacogenetics, idiosyncrasies and drug allergies, selective toxicity in a single organism or in different species, drug actions on properties and functions of membranes
- Drug metabolism
- Distribution and transport of drug molecules between biologic compartments

# New Pergamon Series

## International Series of Monographs in Natural Philosophy

Edited by D. ter Haar, *University  
Reader in Theoretical Physics, Fellow  
of Magdalen College, Oxford*

Although "Natural Philosophy" is the old-fashioned name of what is nowadays called "Physics", it not only describes so much more aptly the true occupation of a physicist, but also suggests the interplay between physics and such disciplines as mathematics, astronomy and geology. For these reasons it was decided to call this new project a "Series in Natural Philosophy" rather than a "Series in Physics, Astrophysics, Geophysics" (etc.).

The emphasis will be on theoretical rather than experimental studies, although occasionally books of the latter type will appear.

A fair proportion of these monographs will deal with aspects of Astrophysics, and one of the early volumes will span the three disciplines of Physics, Astrophysics and Geophysics.

## Quantum Mechanics

A. S. Davydov, *Lomonosov Moscow  
State University*

This volume, the first in the series, is an introduction of quantum electrodynamics, nuclear theory or solid state theory.

### Partial Contents:

The basic concepts of quantum mechanics; change of quantum states in time; The connection between quantum mechanics and classical mechanics; Elementary representation theory; The simplest applications of quantum mechanics; The motion of a particle in a central field of force; Approximate methods for evaluating eigenvalues and eigenfunctions; The foundations of a quasi-relativistic quantum theory of motion of a particle in an external field.

International Series of Monographs  
in Natural Philosophy, Volume 1

696 pages/August 1965 90s./\$15.00

## Time and Space, Weight and Inertia

A. D. Fokker, *formerly Teyler  
Professor, University of Leyden*

Presents a new approach to several advanced topics using Einstein's theory of relativity.

### Contents:

Foundations, One-plus-one dimensional chronogeometry; The chronogeometry of time and space; The Lorentz transformations; Rotations and accelerations in terms of pseudo-revolutions; Metric and other tensors; Dynamical relationships; The dynamical tensor; The equations of the theory of electrons; Accelerating and curving events; Geodesic adaptations; The field equations and the spherical gravitational field.

International Series of Monographs  
in Natural Philosophy, Volume 2

206 pages/July 1965 63s./\$10.00

## Interstellar Gas Dynamics

S. A. Kaplan, *Gorky University*

The first systematic presentation of the basic ideas and methods of interstellar gas dynamics in world literature.

### Partial Contents:

*Distribution and motion of interstellar gas.* Composition of the interstellar medium; Cloud structure of interstellar gas. The intercloud medium and galactic halo; Description of some emission nebulae; *Physical state of the interstellar gas.* Ionization fronts; Hydro-magnetic discontinuities; *Equations of motion of the interstellar gas:* Motion of ionization fronts; Interstellar turbulence.

International Series of Monographs  
in Natural Philosophy, Volume 3

140 pages/September 1965 40s./\$6.50

## Quantum Field Theoretical Methods in Statistical Physics

A. A. Abrikosov, L. P. Gor'kov and  
I. Ye Dzyaloshinskii

Describes recently developed techniques to describe many-particle systems in detail and applications to such systems as liquid helium, helium 3 and superconductors.

### Contents:

Properties of many-particle systems at low temperatures; Quantum field theoretical methods at  $T=0$ ; The diagram technique at finite temperatures; Fermi liquid theory; System of interacting bosons;

Electromagnetic radiation in an absorbing medium; Theory of superconductivity; Transport equation for excitations in a Fermi liquid; References; Index.

International Series of Monographs  
in Natural Philosophy, Volume 4

360 pages/December 1965

70s./\$12.00

## Ready this Autumn

### Ferromagnetic Resonance

Edited by S. V. Vonsovskii,  
*Corresponding Member of the  
USSR Academy of Sciences*

A collection of articles on the phenomenon of resonant absorption of a high-frequency electromagnetic field in ferromagnetic substances.

### Partial Contents:

Magnetic resonance in ferromagnetics—S. V. Vonsovskii; Phenomenological theory—G. V. Skrotskii and L. V. Kurbatov; Magnetic resonance as excitation of spin waves—E. A. Turov; Relaxation processes—M. I. Kaganov; Ferromagnetic resonance in metals—E. A. Turov.

International Series of Mono-  
graphs in Solid State Physics

Approx 352 pages

November 1965

Approx 60s./approx \$9.00

an exponential relation  $P = 1 - e^{-d}$ , between dose,  $d$ , and proportion of hosts responding,  $P$ ; that  $P$  will be unaffected by splitting a total of  $d$  organisms into several smaller doses  $d_i$ ; a mean response time,  $\bar{T}$ , tending to constancy\* for  $d$  less than the  $LED_{50}$ , with  $\bar{T}$  inversely related to  $\log d$  for values of  $d$  exceeding the  $LED_{50}$ ; the variance of  $\bar{T}$ ; the median and variance of the viable counts for a given dose at different times after inoculation; the probability that a given clone has been extinguished by a given time after inoculation; and the probability for a given dose that  $O$  is largely made up of 1, 2, ... or  $d$  clones\*. The last prediction is often phrased as the probability that a host given a dose of known size will respond owing to the multiplication of 1, 2, ... or  $d$  inoculated organisms. The model can be elaborated to include heterogeneity in host resistance, whose degree may be estimated independently by each type of observation such as viable counts or response times. Moreover, the arguments can be used in reverse to estimate  $p$ ,  $O$ ,  $\lambda$ , and  $\mu$  from epidemiological data like the distribution of incubation periods in epidemics of typhoid and streptococcal sore throat<sup>15</sup>. Some of the predictions have long been used to determine the applicability of stochastic models, two examples being dose-response curves<sup>16</sup> and responses to single clones<sup>17</sup>, first discussed in 1931 and 1934 respectively. The hypothesis of the IED makes only one prediction: that the slope of the dose-quantal response curve is infinite when the hosts are uniform in resistance.

The outcome of previous investigations has tended to favour a stochastic mechanism. The slopes of dose-quantal response curves are almost never greater than predicted, whereas co-operation is consistent with any slope up to infinity, and high values do in fact occur in titrations of toxic chemicals and killed organisms<sup>4,11</sup>. Subdivision of the total dose does not affect per cent response<sup>18</sup>. The mean response time appears to tend to constancy at  $d < LED_{50}$  (refs. 12 and 19), and otherwise to vary inversely with  $\log d$ <sup>12,13</sup>. Most hosts that respond to doses  $< LED_{50}$  of a mixture of distinguishable variants of the same pathogen are expected to contain preponderantly 1 clone, but the results do not usually conform to prediction because the organisms appear to interact at some stage during infection<sup>4,13</sup>. Nevertheless, inoculated organisms evidently behave independently in respect of their ability to form discrete visible foci in internal organs, as shown by the number of foci being proportional to the dose<sup>7</sup> and by each focus containing only 1 clone, although a mixture of distinguishable clones is inoculated<sup>4,11</sup>. A finding inexplicable on stochastic possibilities 1 and 2 is that the course of fatal infections in mice given *Salmonella typhimurium* by intraperitoneal injection is apparently determined by the whole dose,  $d$ , and not by an 'effective fraction',  $pd$ <sup>13</sup>. It is now clear that this is to be expected if the infection conforms to a birth-death process<sup>14</sup>.

The distinction between deterministic and birth-death mechanisms can be made in at least three other ways:

(1) By measuring the value of  $\mu$ . This can be done directly in bacterial infections by obtaining  $\lambda - \mu$  from colony counts and by measuring  $\lambda$  alone by the super-infecting phage technique<sup>20</sup>. The birth-death model requires  $\lambda > \mu > 0$  throughout the infection, whereas  $\mu$  might be zero on a deterministic model when the viable count increases. Such measurements would also test a particularly suspect prediction of the birth-death model which follows from  $p = 1 - (\mu/\lambda)$ : that large changes in  $LED_{50}$  can result from minute changes in  $\lambda$  or  $\mu$ .

(2) By determining the growth curves for non-responders given doses differing in size. The birth-death model predicts that the smaller the dose, the sooner will the median viable count fall, whereas on a deterministic model postulating that the decisive event occurred some time after inoculation, the curves might be identical whatever the dose. Mice have been given 0.03 or 0.000075  $LD_{50}$  of *Salmonella paratyphi* B by intraperitoneal injection

( $1LD_{50} = 10^7$  organisms), but there was no appreciable difference between the two sets of colony counts.

(3) By testing all the data from an experiment for internal consistency. For example, it would be inconsistent on any model to postulate small differences in host resistance to account for a dose-mortality curve when viable counts showed the differences to be gross. We have analysed the data of Meynell and Meynell<sup>12</sup> in the light of the birth-death model<sup>14</sup>, and find considerable discrepancies between observation and prediction, as follows.

(a) The dose-mortality curves flatten out too much at small doses. This is explicable either by a proportion of highly susceptible mice (suggested by Shortley and Wilkins<sup>1</sup>) or by an important cause of mortality independent of the bacterial infection.

(b) The estimates of  $\lambda$  obtained from  $p = 1 - (\mu/\lambda)$  and from the net bacterial growth rate  $\lambda - \mu$  are ridiculously high, as mentioned by Shortley and Wilkins<sup>1</sup>, and correspond to doubling times between 8 and 0.02 sec.

(c) At doses not leading to a response the viable counts show a more consistent upward trend with time than predicted.

(d) The observed variance of viable counts is too high at high doses but too low at low doses.

(e) The logarithmic variance of viable count does not increase with time as would be expected if the variability of  $\lambda - \mu$  was important.

These discrepancies can only be explained by radical changes in the model. The most striking anomaly is (b). Shortley and Wilkins<sup>1</sup> appear to favour an explanation resembling stochastic possibilities 1 and 2 by suggesting that most of the dose is rapidly killed, and the survivors are subject to a birth-death process. However, many viable counts<sup>12</sup> provide no support for this explanation.

Further difficulties arise in analysing epidemics, where the dose cannot be measured. The basic birth-death model<sup>14</sup> does not then permit the separate estimation of all the parameters, but this becomes possible by relaxing the assumption that  $O$  is effectively infinite. The resulting estimates of  $\lambda$  are suspiciously small, with estimated doubling times of the order of 100 times longer than the *in vitro* values<sup>12</sup>. This is in striking contrast to the opposite effect from experimental infections, noted in (b) above.

The experimental evidence considered in detail is therefore by no means wholly in favour of any form of stochastic mechanism, despite the fact that the overall picture provided by the basic birth-death model corresponds remarkably well to what is found in practice. The strongest observation in support of some form of stochastic mechanism is the relatively small slope of dose-quantal response curves in infections as compared to those observed in response to toxic agents<sup>11</sup>. Even this could be accounted for on a deterministic model by arguing that host variation in response to infection would necessarily be larger than to a toxin because the outcome of inoculation is undecided as long as any organisms remain viable in the host, often a period of weeks, so offering greater scope for fluctuation in host resistance which might, moreover, depend on many host functions, each fluctuating independently.

Whichever model is considered, the distribution of host resistance, if allowed for, is usually assumed to be unimodal, whereas Shortley and Wilkins<sup>1</sup> conclude from their examination of reported dose-quantal response curves in terms of a stochastic mechanism that resistance is often distributed into two almost homogeneous groups. However, it should be noted that the compound exponential curve then predicted by all stochastic models is very insensitive to variability in  $p$  (ref. 23) and does not enable the precise form of variability to be easily determined. In an earlier examination of the two-point distribution, Armitage<sup>24</sup> said "the purpose of this discussion is merely to show that some sets of data can be fitted by a two-point distribution and that a reasonably good fit can be made fairly quickly". With a two-point distribution, there are

three parameters (the two values of  $p$ , and the proportion of hosts of each type) to be adjusted at will, so a good fit is likely to be obtained to almost any set of rather imprecise data like those obtained from infectivity titrations<sup>11</sup>. It is dangerous to assert too dogmatically that a two-point distribution of  $p$  is implied by observed curves unless a variety of other distributions has been examined and found wanting. In our view, Shortley and Wilkins<sup>1</sup> do not provide adequate support for their extensive fitting of two-point distributions to dose-response data, and, indeed, they show that one set approximates well to an integrated log-normal distribution with large variance (their Fig. 8), such as would be consistent with a very heterogeneous population of hosts the resistances of which were distributed unimodally.

A bimodal, or indeed any irregular distribution of host resistances, would also reveal itself in the distributions of individual response times to a given dose, provided the two groups of hosts did not differ so much that the doses produced responses in only the more susceptible group. Such distributions are known in mice infected by pneumococci<sup>12,13</sup> or tubercle bacilli<sup>14</sup> and possibly in infection by tumour viruses<sup>15,17</sup>, but some examples arise from trivial causes like non-specific death following inoculation<sup>16</sup>, inadequate chemotherapy<sup>18</sup>, cross-infection<sup>19</sup>, and errors of calculation<sup>6</sup>. Convincing examples are difficult to find, and, in most infections, the logarithms of individual response times appear to be unimodally distributed, often approximately normally<sup>20,21,22,23</sup> with a variance independent of dose<sup>24,25</sup>. This suggests that not only is host resistance unimodally distributed, but also that the response times are not influenced by partial immunity acquired during the infection. One would suppose that the anti-microbial mechanisms responsible for acquired immunity begin to act more efficiently at some time after inoculation. Those members of a dose-group which responded before this time would, therefore, be in their initial state, whereas the course of infection in those which responded later would be modified, for example, if the net microbial growth fell so that each response took longer to occur than would otherwise have been the case (see Fig. 1c in ref. 8). In other words, the hosts, though homogeneous in resistance initially, would become heterogeneous during the experiment. In the few systems in which this appears to occur<sup>26,27</sup> the distributions of individual log response times have greater variance and skewness at small doses than at large doses, which implies that the longer response times associated with small doses give anti-microbial mechanisms a greater chance to take effect. The fact that

the majority of observed distributions are not of this kind and, indeed, appear to be the same for all doses might mean that antimicrobial mechanisms entirely fail to develop in any individual that responds. The other extreme is that these mechanisms develop in each individual but are either completely ineffectual, so that the infection progresses undisturbed, or completely effective and prevent the response. That is, the mechanisms underlying acquired immunity may generally exert an all-or-none effect on the infection which provokes them.

## SPECTRAL DATA FROM THE COSMIC X-RAY SOURCES IN SCORPIUS AND NEAR THE GALACTIC CENTRE

By R. GIACCONI, H. GURSKY and J. R. WATERS

American Science and Engineering, Inc., Cambridge, Massachusetts

**D**URING two rocket flights conducted from White Sands Missile Range on August 28, 1964 (flight I), and October 28, 1964 (flight II), we have obtained information regarding the spectral composition of the X-ray source in Scorpius (ScoX-1) and those along the Galactic equator in the vicinity of the Galactic centre. The results were obtained from two separate detectors and extend over the spectral region 1–25 keV. We find that the radiation from ScoX-1 extends from 15 keV to at least 2.5 keV, and that the spectral distribution is not consistent with black-body radiation. The radiation from the region along the Galactic centre extends to about 25 keV. The latter region apparently contains several distinct X-ray sources as reported by Giacconi *et al.*<sup>1</sup>, Bowyer *et al.*<sup>2</sup> and Fisher *et al.*<sup>3</sup>.

Since the discovery of cosmic X-ray sources by Giacconi *et al.*<sup>4</sup> in 1962, only gross information regarding the spectral composition of the radiation has been reported. In the same paper an effective wave-length near 3 Å was reported based on atmospheric attenuation and the difference in counting rate in two separate Geiger counters. Giacconi *et al.*<sup>5</sup> afterwards reported that the spectrum was consistent with a black-body temperature of about 10<sup>7</sup>°K. Bowyer *et al.*<sup>6</sup> attempted to measure the spectral composition of radiation from the Crab Nebula between 1 and 10 keV by making observations in two independent Geiger counters. Later, they published<sup>7</sup> a critical evaluation of their experiment which showed that one of the counters did not function as expected. In the same paper they presented results on the atmospheric attenuation

of X-radiation from the Scorpius source which was consistent with a black-body temperature of  $2-3 \times 10^6$  °K. In another experiment X-radiation from the Crab has been observed between 20 and 60 keV by Clark<sup>7</sup> using balloon-borne instrumentation.

Discussions of the source mechanism for the generation of the observed X-rays has centred on three possibilities: (1) black-body radiation from a neutron star; (2) radiation from an optically thin hot plasma; (3) synchrotron radiation from high-energy electrons in a weak magnetic field. Specific literature citations appear in refs. 5 and 7 cited here and in a review article by Giacconi and Gursky<sup>8</sup>.

We are reporting here spectral data obtained by placing absorbers in front of the Geiger counters during flight I and by performing a pulse height analysis of the output of a sodium iodide (NaI) scintillation counter during flight II. The several sources along the Galactic equator could not be resolved with these counters and all contribute to the spectral data from that region. Other results from these rocket flights have been reported by Giacconi *et al.*<sup>9</sup>, which demonstrated the separation between ScoX-1 and the sources near the Galactic centre, and by Oda *et al.*<sup>10</sup>, which presented the results of the measurement of the angular diameter of ScoX-1.

The Geiger counter detector used during flight I of this experiment was a bank of twelve individual argon-filled counters with beryllium windows of 0.0 mg/cm<sup>2</sup> thickness and a total sensitive area of about 70 cm<sup>2</sup>. The efficiency, calculated as the product of the absorption in the gas filling and the transmission of the window, lies above 10 per cent between 17 keV and 1.2 keV and peaks at between 3 and 4 keV. This computed efficiency was checked experimentally by exposing counters to the beam from a tungsten target, windowless X-ray tube operated from 1.8 to 10 kV. The observed counting rates were in agreement over the entire range of voltage with those predicted using thick target yield curves and the computed counter efficiency.

The Geiger counters were equipped with rectangular collimators which limited the field of view to 15° full width at half maximum (FWHM) in the direction of rotation of the rocket and 20° FWHM in the direction of the rocket long axis. The counter bank was mounted so that its axis of maximum sensitivity made an angle of 80° with respect to the long axis. Two filters, F1 of 7.04 mg/cm<sup>2</sup> of beryllium and F2 of 1.72 mg/cm<sup>2</sup> of mylar, were placed in front of the detector and were sequentially removed during the flight to allow measurements for approximately equal time-intervals of the X-ray fluxes with F1 and F2 in place, F1 alone in place, and no filter.

The motion of the rocket during this flight (flight I) consisted of a rapid rotation with a period of 0.55 sec about the long axis plus a slow precession of the rotation axis with a period of 83 sec along a cone of a small opening angle. The X-ray source regions were observed during each rotation but, because of the low counting rates, data from successive rotations were added in order to obtain sufficient statistical precision.

During each rotation the detector swept out a band on the celestial sphere the width of which, 20°, equalled that of the collimator. The precession results in an approximately sinusoidal variation of the angle of closest approach of a given celestial object to the centre of this band. During each precession cycle the centre of the band came within 2° of ScoX-1 and moved along the Galactic equator between  $l_{II} = 2^\circ$  to  $l_{II} = 27^\circ$ .

Three full precession cycles were recorded during the rocket flight, and since a filter change occurred almost in phase with the precession we have essentially a complete precession cycle of data for each of the three filter conditions. The data from the precession cycle with no filter in place have been the subject of a previous paper<sup>6</sup>. The counting rates with background subtracted observed

Table 1. COUNTING RATE OBSERVED IN THE TWO-SOURCE REGIONS WITH AND WITHOUT FILTERS

Filter condition	Source region	Counting rate measured c.p.m.	Attenuation relative to no filter
No filter	ScoX-1	620 ± 20	1
F1	ScoX-1	440 ± 18	0.71 ± 0.04
F1 + F2	ScoX-1	350 ± 17	0.56 ± 0.03
No filter	Gal cen	350 ± 18	1
F1	Gal cen	240 ± 18	0.70 ± 0.06
F1 + F2	Gal cen	210 ± 15	0.62 ± 0.05
Typical background rate		30 c.p.m.	

with the three filter conditions when the detector crossed ScoX-1 and crossed the region along the Galactic equator are listed in Table 1. The counting rates represent an average over the same fraction of the precession cycle for the three cases. Listed also is the attenuation, defined as the ratio of the counting rates for the two filter combinations compared with no filter.

The significance of the attenuation factor can be partially understood from the following arguments. Photons at 2.5 keV will give the observed attenuation of about 0.7 per filter. In order to obtain the same attenuation factor in the case of a distribution of energies, the number of lower energy photons present, which are absorbed more strongly, must be compensated for by high-energy photons which are absorbed less strongly. Thus, there must be comparable numbers of photons above and below 2.5 keV. The magnitude of the attenuation depends on the true spectral distribution and can be calculated from the relation:

$$\text{Attenuation} = \int \varphi(\lambda) e^{-\mu(\lambda)x} \epsilon(\lambda) d\lambda / \int \varphi(\lambda) \epsilon(\lambda) d\lambda \quad (1)$$

where  $\varphi(\lambda)$  is an assumed spectrum in terms of number of photons per unit wave-length interval,  $\epsilon(\lambda)$  is the counter efficiency,  $\mu(\lambda)$  is the linear absorption coefficient of the filter and  $x$  is the thickness of the filter. We performed this calculation for three assumed spectra, namely, (1) a power law spectrum of the form:

$$\varphi(\lambda) = A\lambda^{-(\alpha+1)} \quad (2)$$

Equation (2) is equivalent to a distribution of the form  $\nu^{-\alpha}$  ( $\nu$  = frequency) when the spectrum is expressed in terms of power per unit frequency interval.

(2) An exponential spectrum of the form:

$$\varphi(\lambda) = (A/\lambda) \exp(-hc/\lambda kT) \quad (3)$$

Except for the weak energy dependence of the Gaunt factor this spectral distribution describes free-free emission by electrons having a Maxwellian distribution of energy.

(3) A thermal spectrum of the form:

$$\varphi(\lambda) = A\lambda^{-4} [\exp(hc/\lambda kT) - 1] \quad (4)$$

The quantity  $A$  that appears in these three distribution laws is a constant that can be determined from the relation:

$$A = N / \int \varphi(\lambda) \epsilon(\lambda) d\lambda \quad (5)$$

where  $N$  is the observed counting rate.

For each of the distribution laws and for each filter condition, equation (1) was evaluated by numerical integration for a series of values of  $\alpha$  in the case of the power law spectrum and of  $T$  in the case of exponential and thermal spectra. The observed attenuations for ScoX-1 are obtained with  $\alpha = -1.1 \pm 0.3$  for a power law spectrum, with  $T = (3.8 \pm 1.8) \times 10^7$  °K for an exponential spectrum, and  $T = (9.1 \pm 0.9) \times 10^6$  °K for a black-body spectrum. The listed uncertainties result from the statistical fluctuations expected from the total accumulated counts. Within the precision of the measurement, the spectrum from the two-source regions is the same over the interval of wave-lengths to which the Geiger counter is sensitive. Furthermore, it is not possible to decide between the three spectral types from these data alone.

Additional spectral results come from the observation during flight II of the same two-source regions by an NaI(Tl) crystal with area of 38.5 cm<sup>2</sup> and a thickness of 1 mm covered by 6.9 mg/cm<sup>2</sup> of aluminium. The crystal was

Fig. 1. Azimuthal distribution of counts observed in NaI detector

viewed by a 7188 OBS photomultiplier and the combination had a measured resolution of 48 per cent FWHM at 22 keV. The detector field of view was limited to  $5^\circ \times 25^\circ$  FWHM and the detector was mounted with its axis at  $60^\circ$  from the long axis of the rocket. During the flight this detector scanned substantially the same source regions in the sky as did the Geiger counters in flight I, and the rocket motion was comparable with that of flight I.

The results from this detector consisted of those photomultiplier pulses above a threshold equivalent to about 8 keV. These were stretched to 1 ms with their pulse height preserved and telemetered in real time from the rocket. Pulses from successive spins of the rocket were summed as a function of both pulse height and rocket azimuth. The azimuthal distribution of all telemetered pulses is shown in Fig. 1. Sources are apparent at azimuths of  $2^\circ$  and  $26^\circ$  which correspond respectively to traversal of the regions containing ScoX-1 and the Galactic equator. We have assumed that the same X-ray sources are responsible for the radiation detected in the NaI and Geiger counter detection systems.

The differential pulse height distributions of the data within the source regions are shown with background subtracted in Fig. 2, as well as the background spectrum itself. The data below 10 keV show the cut-off resulting from the electronic threshold. Above 10 keV the distribution of pulse heights observed in the two-source region is markedly different from the background distribution. The distribution observed from ScoX-1 is consistent with a cut-off in the spectrum at about 15 keV, whereas the radiation from the Galactic equator region extends to higher energies and there is evidence for a possible peak at 20 keV from the same region. The observation of this peak must be regarded as only tentative because of the low statistical precision of the results; however, this feature cannot be an instrumental effect since it does not appear in either of the other two spectra.

The ambiguity in the choice of spectral distribution law that arises from the Geiger counter data alone can be partially resolved by considering the NaI data as well. The counting rates observed for the two-source regions by the two detectors are listed in Table 2. The ratio of counting rates for ScoX-1 is  $(14 \pm 3):1$ , which can be obtained for either a power law or exponential spectral distribution with the parameters determined from the Geiger counter data. To fit a black-body distribution, however, requires a temperature of  $(17 \pm 1) \times 10^6$  °K which cannot be reconciled with the Geiger counter data.

Table 2. COUNTING RATES AND ABSOLUTE FLUXES OBSERVED FOR THE TWO-SOURCE REGIONS

Numbers listed for 1–10 keV are derived from Geiger counters and those listed for >8 keV are derived from the NaI detector. The listed errors are based on the count statistics and in the case of the integrated power and flux in the 1–10 keV range include the effect of the uncertainty of the spectral index

	Counting rate counts/cm <sup>2</sup> -sec	Integrated power ergs/cm <sup>2</sup> -sec	Integrated flux photons/cm <sup>2</sup> -sec
ScoX-1			
1–10 keV	$16.8 \pm 0.6$	$(1.61 \pm 0.4) \times 10^{-7}$	$32 \pm 6$
>8 keV	$1.2 \pm 0.3$	$(8.3 \pm 0.8) \times 10^{-8}$	$18 \pm 4$
Galactic equator			
1–10 keV	$4.3 \pm 0.2$	$(0.4 \pm 0.1) \times 10^{-7}$	$8 \pm 2$
>8 keV	$0.67 \pm 0.15$	$(1.9 \pm 0.4) \times 10^{-8}$	$0.8 \pm 0.2$

The black-body temperature consistent with the Geiger counter data predicts a ratio of about 200:1. This analysis applied to the ratio of counting rates observed in the Galactic counter region yields the same general results; namely, that the ratio can be fitted with either an exponential or power law spectrum but that a black-body spectrum yields an insignificant flux in the NaI detector compared with what is observed. It is possible that a series of black-body sources gives rise to the observed radiation which, however, implies that one of the sources has a temperature of several times  $10^7$  °K.

In the case of ScoX-1, if one wishes to fit a thermal spectrum of the order of  $10^7$  °K as is consistent with the Geiger counter data alone plus a high-energy tail to account for the NaI results, the power in the tail must be the order of 25 per cent of that in the thermal portion of the spectrum and to fit a lower temperature requires an even more substantial non-thermal tail. Thus, if a neutron star is postulated as the X-ray source, a large fraction of the observed flux cannot arise from the black-body radiation from that object.

More generally the absence of a substantial thermal contribution to the spectrum indicates that the observed X-rays are being generated in regions that are optically thin. Whether the X-rays are generated in a hot plasma or by the synchrotron process cannot be determined on the basis of these data except for noting that, in a hot plasma line, emission and edge discontinuities can arise, either of which could account for the peak at 20 keV for which there is some evidence from the NaI detector. The synchrotron process cannot give rise to such features.

Table 2 lists the counting rate, the integrated power and photon flux observed in the two-source regions by the two detectors. For ScoX-1 the counting rates are corrected for the shadowing of the collimators and result from the fact that the detector axis comes only within  $2^\circ$  of the source. No such correction was made in the case of the sources near the Galactic centre. In the 1–10-keV region the integrated power and photon flux were obtained by assuming a power law distribution with the spectral index obtained from the filter attenuation of the Geiger counter results. The uncertainty in the spectral index yields the uncertainties in the integral quantity. In the

Fig. 2. Pulse height distribution of counting rates observed in NaI detector

> 8 keV region the integrated power and photon fluxes were obtained by summing over the NaI pulse-height distribution.

In summary, the results presented here indicate the following:

- (1) The ratio of the counting rate in the Geiger counters to that in the NaI detector is not consistent with a single thermal spectrum.
- (2) The NaI detector does not detect significant radiation from ScoX-1 beyond about 15 keV, whereas radiation is observed from the Galactic centre region to beyond 20 keV. The minimum detectable flux density at 20 keV (defined as equivalent to 1σ above background) is about  $3 \times 10^{-17}$  ergs/cm<sup>2</sup>-sec (c/s). Clark<sup>1</sup> measures a flux of  $(2.4 \pm 0.6) \times 10^{-17}$  ergs/cm<sup>2</sup>-sec (c/s) over the range of 20–40 keV from the Crab Nebula. The power from ScoX-1 at these high energies is thus considerably below what is emanating from the Crab even though at lower energies (1–10 keV) ScoX-1 is the brighter object as reported by Friedman<sup>2</sup>.
- (3) For both source regions the attenuation of the counting rate in the Geiger counters by the filters indicates

that the X-ray flux below 2.5 keV is comparable with that above 2.5 keV. This result does not agree with that reported by Fisher<sup>3</sup> that little or no radiation is present below 4 keV from these sources.

The work reported here was sponsored by the U.S. National Aeronautics and Space Administration, Office of Space Sciences, under contract NASw-898.

## RECENT PROGRESS IN DETERMINING THE ZONAL HARMONICS OF THE EARTH'S GRAVITATIONAL POTENTIAL

By D. G. KING-HELE

Royal Aircraft Establishment, Farnborough

DURING the past year significantly better values have been found for the coefficients of the zonal harmonics in the Earth's gravitational potential. Several authors have given improved sets of values, obtained from analysis of satellite orbits, and the different sets of values agree well, probably because orbits are now available which have a wide variety of inclinations to the equator.

The coefficients  $J_n$  of the zonal harmonics are defined as follows. The gravitational potential  $U$  at an exterior point distant  $r$  from the Earth's centre, and having geocentric latitude  $\varphi$ , is written in a series of spherical harmonics as:

$$U = \frac{GM}{r} \left\{ 1 - \sum_{n=2}^{\infty} J_n \left( \frac{R}{r} \right)^n P_n(\sin \varphi) \right\} \quad (1)$$

where  $G$  is the gravitational constant,  $M$  the mass of the Earth, and  $R$  the Earth's equatorial radius.  $P_n(\sin \varphi)$  is the Legendre polynomial of degree  $n$  and argument  $\sin \varphi$ , and the  $J_n$  are constant coefficients. Equation (1) does not take into account the small variation of  $U$  with longitude, and represents an average over all longitudes.  $GM$  is often taken as 398,802 km<sup>3</sup>/sec<sup>2</sup> and  $R$  as 6,378.163 km, but the last figure in each of these constants is slightly uncertain.

Values of the coefficients of the even zonal harmonics,  $J_2, J_4, \dots, J_{12}$ , may be obtained by analysing the rates of rotation of the orbital planes of  $m$  or more satellites in appreciably different orbits, if it is assumed that  $J_{2m+1}, J_{4m+1}, \dots$  are zero. Similarly, values of  $J_1, J_3, \dots, J_{11}$  may be found by analysing the amplitudes of the long-period oscillations in eccentricity (and other orbital elements) for  $m$  or more satellites in appreciably different orbits.

Recent sets of values of the even and odd coefficients are listed in Tables 1 and 2. It should be emphasized

that the number of coefficients evaluated is a matter for judgement and personal preference. The author who evaluates only a small number of coefficients has to meet the objection that he would obtain a better fit by using an extra coefficient; the author who evaluates a large number of coefficients has to meet the objection that he has fitted a polynomial of too high a degree and that the solution gives a potential which oscillates in an unrealistic manner. So a set with a large number of coefficients is not likely to be any more accurate than a set with a smaller number of coefficients. In fact it can be shown that the perturbations to close satellite orbits caused by the different sets of coefficients in Table 1 (or Table 2) are almost identical for satellites with orbital inclinations between 25° and 90°. Some divergence occurs at inclinations below 25° and there is an urgent need for a satellite in a stable orbit at an inclination between 10° and 20° in order to improve further the values of the coefficients.

Table 2. RECENT SETS OF VALUES OF THE ODD  $J_n$

Authors	$10^4 J_1$	$10^4 J_3$	$10^4 J_5$	$10^4 J_7$	$10^4 J_{11}$
Guler and Newton <sup>1</sup>	-2.69	-0.01	-0.63	0.21	—
King-Hele, Cook and Scott <sup>2</sup>	-2.56	-0.16	-0.44	0.12	—
Kozai <sup>3</sup>	-2.56	-0.18	-0.38	0.04	0.30

A few comments should be made on Tables 1 and 2. The standard deviations in the values, as derived by the authors, are not given, because the error due to neglecting coefficients of degree higher than those evaluated is probably greater than the errors given by most of the authors. A better impression of the likely errors is obtained by comparing the different sets of values: this suggests the errors in most of the coefficients may be of order 0.1. It should be emphasized, however, that the values of the complete potential, not the individual coefficients, are of prime importance, and that the different sets of coefficients give rise to closely similar potentials, despite the differences in individual coefficients.

It is only by chance that the three values of  $J_1$  in Table 1 are so close, and  $J_2$  may well take a slightly different value when near-equatorial orbits can be analysed; even so, the value seems likely to remain between 1,082.6 and

Table 1. RECENT SETS OF VALUES OF THE EVEN  $J_n$

Authors	$10^4 J_2$	$10^4 J_4$	$10^4 J_6$	$10^4 J_8$	$10^4 J_{10}$	$10^4 J_{12}$
King-Hele and Cook <sup>1</sup>	1,082.64	-1.52	0.57	0.44	—	—
Kozai <sup>2</sup>	1,082.63	-1.63	0.59	-0.15	-0.16	-0.29
Smith <sup>3</sup>	1,082.64	-1.70	0.73	-0.46	-0.17	-0.22
						0.19

$1,082.7 \times 10^{-4}$ . If  $10^4 J_2 = 1,082.64$ , the value for the Earth's flattening, using the conventional formula<sup>1</sup>, is  $1/298.26$ .

The coefficient  $J_2$ , which expresses the Earth's tendency towards a pear shape, has a significantly greater numerical value than seemed probable two years ago, being near  $-2.6 \times 10^{-4}$  rather than  $-2.4 \times 10^{-4}$ . With the second set of values for the odd harmonics in Table 2, the sea-level surface at the north pole is 39 m farther from the equator than sea-level at the south pole.

There has also been important progress recently in the evaluation of the tesseral harmonics, which indicate the variation of  $U$  with longitude; but this topic is outside the scope of the present article.

## NEWS and VIEWS

### Social Studies In Britain

IN the House of Commons on June 2, Mr. A. Croeland, Secretary of State for Education and Science, announced the publication of the Report of the Heyworth Committee on Social Studies (see p. 559 of this issue of *Nature*). He said that the Government accepted in principle the Committee's main recommendation that a Social Science Research Council should be appointed by the Secretary of State for Education and Science. It also accepted that there was considerable scope for stronger support and better co-ordination of research in this field, and it believed that the Committee was right in concluding that this could best be achieved with the help of such a Research Council, while maintaining support through the University Grants Committee and, where appropriate, through Government departments. The terms of reference of the new Council, its scope and membership, and the arrangements for budgetary control, would require further consideration, but the Government, while accepting that further provisions should be made for research in urban planning, did not believe that the joint board of the various research councils, proposed by the Committee, would be satisfactory. The Government was, in fact, considering what provision could be made for this purpose, and in a written answer on June 14, Mr. Croeland added that the main reason for not accepting this recommendation was that the Research Councils concerned could not provide the professional skills needed, in addition to scientific advice, in judging needs and proposals for research in this field. Another reason was that under such an arrangement research in urban planning would depend primarily on support from three Research Councils, none of which would have more than peripheral interest in this essentially inter-disciplinary field of work. Mr. Croeland also said that the Government accepted that some increase was desirable in financial support for research in social sciences, but it proposed to await the advice of the Council itself. The Government recognized the important part which social scientists could play in formulating and executing policy and intended to ensure that Government departments were so organized and staffed that information and advice from social scientists were available on an adequate scale. Mr. Croeland stated that, at this stage, the Government could not be expected to comment in detail on other recommendations of the Committee.

### National Survey of Staff employed on Information Work

SIR JAMES COOK writes: "One of the functions of the Office for Scientific and Technical Information (recently set up within the Department of Education and Science) is to consider what additional facilities should be provided within Great Britain to train staff for information departments and special libraries, which are growing in number and size as a consequence of the increasing volume of scientific and technical information. As a first step, the Office is conducting a national survey in order to obtain certain facts, estimates and views on the employment of such staff. This is being done by means of two question-

naires—a short one for management and a longer one for individuals employed on work of this sort. So as to preserve complete anonymity the names of organizations and individuals are not being asked for. The distribution of the questionnaires is being carried out chiefly by Government departments, research associations and other grant-aided bodies. I should be grateful, though, for the hospitality of your columns in order to give general publicity to this survey. Anyone concerned with information work, who does not receive a copy of the relevant questionnaire by July 31, may obtain it, either by writing to the Office for Scientific and Technical Information, or by 'phoning Chancery 1262, Ext. 417'.

### Meteorology at the University of Reading

A DEGREE course in meteorology is to be instituted in the University of Reading from October, 1965. Students accepted for the course will read meteorology, physics and mathematics for three years. The course in meteorology will be concerned with the physics and dynamics of the atmosphere with special attention to problems of weather and climate. Students will attend lectures and laboratory demonstration experiments, will carry out synoptic weather analysis and undertake field observations and experiments.

A particularly favourable circumstance is the presence at Bracknell, only eleven miles away, of the headquarters of the Meteorological Office. This is not only the national centre of weather services but also the largest meteorological research centre in Britain. The authorities of the Meteorological Office have shown great interest in the planning of meteorology in the university and, by visits to Bracknell and in other ways, students will be familiarized with the work of the Office. It is intended to institute also a one-year postgraduate course in meteorology which will lead to the degree of M.Sc. It is expected that entry to this course will be restricted to graduates who have followed the B.Sc. course or have comparable qualifications.

Prof. R. C. Sutcliffe, C.B., O.B.E., F.R.S.

DR. R. C. SUTCLIFFE, director of research in the Meteorological Office, has been appointed the first professor of meteorology. He was educated at Whitcliffe Mount Grammar School, Cleckheaton, the University of Leeds (1922-26) and the University College, Bangor (1926-27). He saw service with the Royal Air Force from 1939 until 1946 on meteorological duties and was demobilized as Group Captain. He has taken a leading position in national and international societies and committees for meteorology and related sciences. He is at present, for example, chairman of one Sub-Committee of the Royal Society and member of several others, a past-president of the Royal Meteorological Society and a member of various Government Committees such as the National Oceanographical Council. He is also closely connected with the World Meteorological Organization, being chairman of its Scientific Advisory Committee, and is

vice-president of the International Association of Meteorology and Atmospheric Physics, and a member of the NATO Advisory Group on Meteorology. He has published numerous scientific articles, etc. His main research interests are in mathematical and dynamical meteorology, its application to weather forecasting, and the detailed investigation of the evolution and development of weather systems.

Prof. W. V. Mayneord, F.R.S.

PROF. W. V. MAYNEORD has been awarded the Gold Medal *Pro Meritis Protectione Contra Radiationem* of the Royal Swedish Academy of Science. The Medal will be presented to Prof. Mayneord at the eleventh International Congress of Radiology, which will be held in Rome in September 1965. Until his retirement in September 1964, Prof. Mayneord was professor of physics as applied to medicine in the University of London, and director of the Department of Physics in the Institute of Cancer Research, Royal Cancer Hospital, London. He was a member of the International Commission on Radiological Protection during 1950-59; from 1950 until 1956 he was chairman of the Commission's committee on protection against high-energy radiations (see *Nature*, 204, 22; 1964).

Central Veterinary Laboratory, Weybridge :

Dr. A. B. Paterson

DR. A. B. PATERSON has been promoted deputy director of the Central Veterinary Laboratory, Weybridge, following the death of Mr. J. L. McGirr. Dr. Paterson graduated from Glasgow Veterinary College in 1941. He joined the staff of the Biochemistry Department at the Central Veterinary Laboratory in 1944 after undertaking postgraduate training in chemistry during the tenure of an Agricultural Research Council grant. After work in the field of metabolic diseases of cattle, he took charge of tuberculin production and research, being promoted senior research officer, Grade 2, in 1950. Dr. Paterson was awarded a Ph.D. degree by the University of London in 1954, and became a Fellow of the Royal Institute of Chemistry in 1958. In 1959 he became senior research officer (Grade 1) in charge of the Virology Department.

Psychiatry in the University of Manchester :

Prof. E. W. Anderson

PROF. E. W. ANDERSON, who has been professor of psychiatry in the University of Manchester since 1949, has been appointed a medical visitor in the office of the Lord Chancellor and will relinquish the chair of psychiatry on September 30.

Prof. W. I. N. Kessel

DR. W. I. N. KESSEL has been appointed to succeed Prof. Anderson, from a date to be arranged. Dr. Kessel is at present assistant director of the Medical Research Council Unit for Research on the Epidemiology of Psychiatric Illness and honorary senior lecturer in the Department of Psychological Medicine of the University of Edinburgh. Dr. Kessel was educated at Highgate School and Trinity College, Cambridge, where he was awarded a B.A. degree in 1945 and M.B., B.Chir. in 1949. In 1958 he obtained the diploma in psychological medicine of the University of London with distinction and was awarded an M.D. (Cambridge) in 1963. After qualification he was for one year a house surgeon in University College Hospital, London, and then held successively posts as house physician in the West Middlesex and St. Mary Abbots Hospitals and medical registrar in St. Stephens Hospital, Chelsea. In 1953 he was appointed to the staff of the Maudsley Hospital where for the next five years he held successively the posts of senior house officer, registrar and senior registrar, for the most part in the Professorial Unit. From 1960 he was for one year honorary senior registrar in the Psychiatric Department of University

College Hospital and since 1961 has held his present appointments in Edinburgh, where he has assumed responsibility for the psychiatric care of patients admitted to the emergency ward at the Royal Infirmary. Dr. Kessel's major research interests are in suicide and attempted suicide, the identification and estimation of psychiatric morbidity in general practice, and studies on the epidemiology of psychosomatic medicine. He is the joint author of a book, *Alcoholism*, and in 1965 he delivered the Milroy Lectures to the Royal College of Physicians.

Electrical and Control Engineering in Battersea College of Advanced Technology : Prof. D. R. Chick

DR. D. R. CHICK has been appointed to a chair in, and the headship of, the Department of Electrical and Control Engineering in Battersea College of Advanced Technology (University of Surrey at Guildford designate). Dr. Chick took his first degree in electrical engineering in 1937 and served in various posts dealing with military radio and radar to the end of the Second World War, in particular with the transmitters at Bawdsey and Christchurch, and earned a joint inventor's award for his work on searchlight radar control. He joined the new research laboratory of Associated Electrical Industries, Ltd., at Aldermaston, as a section leader responsible for developing the company's early interests in nuclear engineering, and later as a group leader he co-ordinated the thermonuclear and reactor engineering. With the late Dr. Petrie he developed a successful radio-frequency travelling-wave accelerator for protons to boost the energy of particles leaving the high-voltage electrostatic generator which his Section had built, and he was awarded an M.Eng. by the University of London for this contribution, also an M.Sc. in physics by the University of Reading for his work on static machines. His engineering contributions to the thermonuclear work culminated in the successful operation of the *Sceptre* series of toroidal accelerators, and he gave overall guidance to the design, construction and operation of the first British research reactor, the 5-MW *Martin* at Aldermaston. For his many original engineering papers he was awarded a D.Eng. degree by the University of London. His work has kept him in close touch with research in many universities in the United Kingdom and overseas. He has spent the past two years with the Vickers research organization.

Geography in the University of Edinburgh :

Prof. J. T. Coppock

DR. J. T. COPPOCK, reader in geography in University College, London, has been appointed to the newly instituted Ogilvie chair of geography. This chair is additional to the chair at present held by Prof. J. Wreford Watson. Dr. Coppock was born and went to school in Wales. After service during the Second World War, mainly in the Middle East, he went up to Queen's College, Cambridge, where he was a Foundation Scholar and obtained first-class honours in both Parts of the Geographical Tripos. After a further year at Cambridge as departmental demonstrator in geography, he was appointed in 1950 assistant lecturer in the Department of Geography in University College, London. Promoted to lecturer in 1952, he was accorded his present status of reader in 1964. During the academic session 1963-64 he was visiting senior lecturer in the Department of Geography at the University of Ibadan, Nigeria. He was awarded the degree of M.A. by the University of Cambridge in 1953 and the degree of Ph.D. by the University of London in 1960. Dr. Coppock's principal research interests have lain in the fields of economic and historical geography with particular reference to the geography of agriculture and the problems of rural land-use and land-use competition. In collaboration with R. H. Best he has published a study of land-use changes in Great Britain, and he has recently been appointed a member of the England Committee of

the Nature Conservancy. He has also a general interest in the application of mechanical and electronic aids in data processing and map making and has published an agricultural atlas of England and Wales with the aid of the University of London computer and in collaboration with the Department of Numerical Automation. Dr. Coppock will take up his appointment on January 1, 1966.

#### U.K. Petroleum Statistics, 1963 and 1964

THE United Kingdom *Petroleum Industry Statistics* for the years 1963 and 1964 have recently been published by the Petroleum Information Bureau on behalf of the U.K. Petroleum Industry Advisory Committee (U.K. *Petroleum Industry Statistics: Consumption and Refinery Production, 1963 and 1964*. Pp. 8. London. Petroleum Information Bureau, 1965). Some interesting and perhaps significant contrasts are revealed. In 1963 total consumption of all products (excluding deliveries for bunkers for ships engaged in foreign trade) was 55,692,382 tons; in 1964, 61,199,662 tons. This consumption was apportioned as between: aviation fuels, 2,238,000 and 2,302,931 tons (1963 and 1964 respectively); motor spirit, 9,044,378 and 10,011,922 tons; industrial spirits, 200,429 and 229,880 tons; white spirit, 139,955 and 142,654 tons; kerosene, 1,673,261 and 1,468,218 tons (burning oil) and 183,962 and 147,869 tons (vaporizing oil); derv fuel, 3,305,230 and 3,636,469 tons; gas, Diesel and fuel oils, 5,453,366 and 6,001,368 tons (gas/Diesel oil) and 22,704,005 tons and 24,804,792 tons (fuel oil); lubricating oils and greases, 1,003,482 and 1,081,440 tons; paraffin wax and scale, 52,438 and 58,797 tons; propane, 99,193 and 147,576 tons; butane, 371,364 and 621,456 tons; methane, nil for 1963, 76,917 tons for 1964; bitumen, 1,314,429 and 1,491,291 tons; chemical feedstock, 2,706,351 and 3,126,828 tons; light distillate feedstock, 900,330 and 1,347,312 tons; refinery gases, 426,619 and 483,046 tons. Thus deliveries into consumption of these products, with the exception of kerosene, showed marked increases in 1964 over the preceding year. The figures for propane, butane, methane, chemical feedstock and light distillate feedstock for 1964 are significant of the rapidly expanding petrochemicals and gas industry.

#### Czechoslovak Society of Arts and Sciences in the United States

THE Czechoslovak Society of Arts and Sciences in the United States is a unique organization (*Nature*, 198, 944; 1963). Its 800 members, of whom one-third are teachers at various universities in the United States, are mostly emigrants from Czechoslovakia who have kept their interest in their home-land alive and burning. The Society held two congresses in the United States: one in Washington, D.C., in 1962, and one in New York in 1964. A recent book, *The Czechoslovak Contribution to World Culture* (edit. by Miloslav Rechcigl, jun. Pp. 682. The Hague: Mouton and Co., 1965. Gld. 58.00), is based mainly on the papers presented at the first congress, but seventeen of the fifty-seven contributions were not presented. The subjects range far and wide over the spectrum of Czechoslovak culture, national and international, past and present. The book is divided into ten parts: literature and literary criticism, linguistics, music and fine arts, history, political science and philosophy, sociology, economics, law, science and technology, and Czechs and Slovaks abroad. The volume is concluded with a bibliography on Czechoslovak arts and sciences containing 1,318 references. Short biographies of the fifty-four authors and an index are also included. The individual contributions vary so much in scope and subject-matter that any reader can find an article or two touching directly on his field of interest. The book is neither an encyclopaedia nor an ordered treatise on Czechoslovakia. To a reader interested in all aspects of Slavistics it can be highly recommended; to a student of Czechoslovakia it is

invaluable. It is expected that a similar volume, based on the 1964 Congress of the Society, will be published in due course.

#### Tumour Research

VOLUME VII, *Fascicles 3 and 4* of the *Archivio Italiano di Patologia e Clinica dei Tumori*, is a beautifully printed and attractively produced volume containing 15 articles on various aspects of the study of tumours. The subjects dealt with include methods of producing experimental cerebral tumours resembling human brain tumours, and the morphological, biochemical and immunological properties of these experimentally produced tumours, the difficulties of transplanting them and the promising future of this field of research. Two articles discuss the anti-tumoral activity of a series of biguanide derivatives tested on Ehrlich ascites tumour. Two articles discuss the effects of urethane on the cells of this tumour. Another article describes the morphological, biochemical and immunological properties of Ehrlich ascites tumour cells which have been submitted to several cycles of freezing and thawing. In a paper on the reliability of a technique for the early serodiagnosis of malignant neoplasia, which is based on identifying a typical phospholipid (malignolipin) in the serum, the authors conclude that Kosaki's technique obtains only a mixture of inorganic ions and pirates from the solvent, but no malignolipin. An article on the treatment of patients with malignant tumours with 2,3,5-triethyleniminobenzoquinone by different methods describes palliative effects on one group of patients with no serious side-effects. A second group showed no deaths in the first year, although deaths were recorded among the controls. The volume ends with an illustrated description of 5 cases of histologically benign tumours of the stomach (haemangio-endotheliomas, lipomas and adeno-papillomas and choristomas (aberrant pancreas)), and the author discusses the great difficulties in differentiating on clinical and radiological data between benign blastomas, choristomas and malignant tumours. All the articles give copious references to the relevant literature.

#### Transplantation Research

THE size of the *Proceedings* of the sixth International Transplantation Conference (five times as thick as the first) is an indication of the attraction this subject has for research, but the progress made so far in overcoming the basic problems of tissue incompatibility seems scarcely to justify its present-day popularity with experimental surgeons (*Annals of the New York Academy of Sciences*, 120, 1-806; 1964). Perhaps the most intensive effort has been directed towards finding means of typing human tissues for histocompatibility, as by this it would become possible to pick from a panel of prospective donors that one whose tissue would be most likely to survive in the recipient. Probably the most valuable test in the long run will be an entirely *in vitro* reaction such as that of Bain *et al.*, in which the blood lymphocytes of prospective donor and recipient are allowed to react together. A clinical section (Volume 2) deals largely with attempts to transplant a great many organs in man and animals. While it includes many interesting descriptions of surgical technique and of the pathology of the grafted organs during the rejection which almost invariably occurred, the value of the information obtained sometimes seems scarcely to justify the experiment—especially where human patients were involved. The ethics of such experiments are considered in a thoughtful survey of human kidney transplantation by Murray *et al.* Even in the few "well-tolerated" human kidney grafts described by Hamburger *et al.*, there were recurrent crises which required treatment with immunosuppressive drugs. It thus appears that the presence of the grafted organ alone may not be sufficient to maintain the state of tolerance,

so that in addition to inducing tolerance before grafting we are faced with the problem of maintaining tolerance in the long term. It may be that the continued presence of donor lymphoid cells, intermingled with those of the host, is necessary for tolerance to be permanent. It is this, no doubt, which prompts the considerable attention which is directed to the part played by lymphoid tissue chimerism in the maintenance of the tolerant state. Unfortunately, no firm conclusions can be reported. As a whole, these *Proceedings* are now rather more specialized than previously, and contain less material of interest to the general immunologist, but they remain the best assemblage of advances in transplantation research.

### Food Preservation

THE report of the C.S.I.R.O. Division of Food Preservation for the years 1962-64 records work carried out under the following headings: physics, food chemistry, plant physiology, microbiology, meat research, fish, fresh fruit and vegetables, frozen fruit and vegetables, dried foods, canning, packaging and irradiation (Pp. vi+77. Sydney: Commonwealth Scientific and Industrial Research Organization, 1964). Microbiological work has included investigations on the relation between chemical composition and spore resistance. The heat resistance of spores from the eighteen organisms studied varied by a factor of more than 700; the principal metal constituent in nearly all species was calcium. The calcium content increased significantly with heat resistance while the magnesium content decreased. Diamino pimelic acid also increased with heat resistance and, on a spore unit basis, this acid and dipicolinic acid hexoamine were highly correlated among themselves and with calcium content and spore weight. Studies on responses of meat-spoilage organisms to changes in environment showed that species of *Pseudomonas*, the main spoilage organisms on fresh meat stored in air, are inhibited in certain other atmospheres. Investigations to apply this to carcass preservation are being continued. Meat research was devoted largely to various aspects of meat quality and to a study of the complex biochemical events occurring in post-mortem muscle. Meat from emaciated animals, in addition to having a higher pH, produces more hydrogen sulphide on heating, with resultant staining of cans, and it was suggested that the addition of lactic acid to the meat before canning would reduce such staining. The effects of the removal of muscle from the bones and of proteolytic enzymes on tenderness were also investigated. A pea sheller developed by the Division gave higher recovery of peas than did commercial viners. The rate of damage was reduced, the quality of peas being comparable with that obtained by hand shelling.

### Palynological Society of India

THE Palynological Society of India was founded by an internationally representative section of palynologists, and was inaugurated on January 5 at Calcutta, during the Combined 51-52 Session of the Indian Science Congress. The Society has undertaken the publication of the *Palynological Bulletin* and the *Journal of Palynology* (both of which are annual publications). The membership of the Society is open to all scientists of all nationalities interested in the study of pollen and spores. There are two types of membership, namely: (1) Life Membership, and (2) Ordinary Membership (apart from Institution Membership), in each of which there are two categories A and B. Institution members and members of category A (Life/Ordinary) are entitled to free copies of both the *Journal of Palynology* and the *Palynological Bulletin*, while those in category B (Life/Ordinary) are only entitled to the *Palynological Bulletin*. The membership fees are as follows: *Life Membership*, Category (A). Rs. 100; 24 dollars; £8 (consolidated). Category (B). Rs. 30; 8 dollars; £3 (consolidated). *Ordinary*

*Membership*. Category (A). Rs. 10; 2.4 dollars; 14s. per annum. Category (B). Rs. 3; 1 dollar; 8s. per annum. *Institution Membership*, Rs. 15; 4 dollars; £1 per annum. *Admission fee*, Rs. 2; 48 cents; 8s. for all categories of membership. Further information and membership forms can be obtained from Dr. P. K. K. Nair, general secretary-treasurer, Palynological Society of India, National Botanic Gardens, Lucknow.

### Testing for Seed Health

PROVISION of disease-free seed in agriculture and horticulture is an important factor in raising productivity of food crops. The International Seed Testing Association, Wageningen (Holland), is working towards the accumulation of sufficient knowledge to be able to specify methods for testing seed health which would command world-wide acceptance. A most timely and welcome contribution to this end, from the Plant Pathology Division, Ministry of Agriculture, The Queen's University, Belfast, has recently been published by the Association (*Seed-Borne Fungi: Descriptions of 77 Fungus Species. Handbook of Seed Health Testing*, Series 4 (1). By J. P. Malone and A. E. Muskett. Pp. ii+179-384. Wageningen: The International Seed Testing Association, 1964. 2.05 dollars). The essential feature of the Ulster method is the plating out of seeds on malt extract agar, with or without previous surface sterilization. It is then necessary to be able to distinguish the truly parasitic fungi from those causing little or no damage, so the *Handbook* gives sufficiently detailed descriptions of 77 species or species groups to provide almost forensic standards for recognition. There are, moreover, 284 excellent photomicrographs and photographs of cultures to assist in diagnosis, all of them the sort of practical views encountered in day-to-day examinations. It should be noted that an effective examination for seed contaminants should declare the greatest risk of disease from the sample, but this does not mean that such an amount will necessarily develop, for disease occurrence needs favourable conditions of environment and host reaction in addition to the presence of a parasite. The problem is complicated by the fact that certain seed contaminants may be symbionts beneficial to the plant (for example, an endophytic fungus on *Lolium* spp.) or they may diminish the activity of more active parasites (for example, *Chaetomium* spp. have been held responsible for the low incidence of disease caused by *Helminthosporium victoriae* on oats in Brazil). On the other hand, such potential food grain contaminants as *Aspergillus fumigatus* and *Claviceps* spp. are dangerous to man and livestock, and many fungi deteriorate seeds stored for food. It is therefore essential to be able to assess seed contamination, or more positively seed health, and the detailed information in the *Handbook* should have ready and wide acceptance.

### University News:

#### Liverpool

DR. J. R. ANDERSON has been appointed to the George Holt chair of pathology. Dr. E. Parry has been appointed senior lecturer in anatomy. The following lecturers have also been appointed: Dr. M. J. Roberts (applied mathematics); A. H. Cookson (electrical engineering and electronics).

#### Manchester

DR. P. G. MURPHY has been appointed to the newly established additional chair of physics. The following lecturers have been appointed: Dr. B. J. G. Johnson and Dr. E. Hutton (chemistry); Dr. F. M. Cole (pathology); N. E. Long and Dr. G. K. Garbett (social anthropology); Dr. R. A. James (astronomy); K. S. Williams (mathematics); R. W. Morgan and R. Morton (mathematical statistics); Dr. J. A. D. Aekroyd (mechanics of fluids); Dr. D. G. Lees (metallurgy); Dr. J. G. Baker and Dr. M. A. H. McCausland (physics); Dr. L. M. Cook (zoology); Dr. J. R. Rintoul (anatomy).

## Newcastle upon Tyne

DR. A. JEFFREY has been appointed to the chair of engineering mathematics from September 1. Dr. E. S. Page, director of the computer laboratory, has been appointed to the chair of computing and data processing.

## Sheffield

DR. P. C. KENDALL has been appointed to the second chair of applied mathematics. The following lecturers have been appointed: Dr. G. C. Bye (ceramics with refractories technology); Dr. D. H. Lewis (botany); T. Shanin (sociology); Dr. D. A. Spears (geology). The title of reader has been conferred on: Dr. J. McKenna (organic chemistry); Dr. B. Stevens (photochemistry); Dr. H. J. V. Tyrrell and Dr. P. A. H. Wyatt (physical chemistry).

## Sussex

THE following appointments have been made: *Professorships*, Dr. J. R. Postgate (microbiology); Dr. D. F. Brewer and Dr. M. W. Thompson (physics). *Senior Lectureships*, N. G. Meadows (electrical engineering); Dr. A. W. Simpson (materials science). *Lectureships*, Dr. R. M. Lynden-Bell (chemistry); D. T. Streeter and Dr. J. D. Thomas (biological sciences); Dr. B. V. Jayawant, P. Lindon and Dr. G. Williams (electrical engineering); Dr. R. D. Doherty and Dr. M. E. Ertl (materials science); Dr. J. R. Ellis (mathematics); Dr. D. Bailein and Dr. E. A. Sanderson (theoretical physics); Dr. J. Byrne (experimental physics); M. S. Halliday (psychology); Dr. J. F. Boissvain (sociology); Dr. R. L. Harris (social anthropology).

## Possible Anti-matter Content of the Tunguska Meteor of 1908

PROF. W. F. LIBBY has written to the Editor stating that it has been brought to his attention that Dr. Lincoln LaPaz, of the University of New Mexico, had published earlier results on several aspects of the Tunguska meteorite, referred to in the article by Prof. C. Cowan, C. R. Atluri and Prof. W. F. Libby entitled "Possible Anti-matter Content of the Tunguska Meteor of 1908", which was published on p. 861 of the May 29, 1965, issue of *Nature*. The references which should have been mentioned were as follows: "Meteorite Craters and the Hypothesis of the Existence of Contraterrene Meteorites", *Contr. Soc. Res. Meteorites*, 2, No. 4 (1941); "Contraterrene Meteorites", *Contr. Soc. Res. Meteorites in Popular Astron.*, 49, No. 5 (May 1941); "The Energy of the Podkamennaya Tunguska, Siberia, Meteoritic Fall ( $\pm 1019,609$ )", *Contr. Meteorit. Soc.*, 4, No. 2 (1948).

## Food Preference and Sensitivity of Taste for Bitter Compounds

DR. E. V. GLANVILLE, Dr. A. R. Kaplan and Mrs. F. Griffin have written to the Editor stating that in the article which appeared under the above title by Drs. E. V. Glanville and A. R. Kaplan (*Nature*, 205, 851; 1965), in the fourth from the last paragraph it was stated that taste "... sensitivity to PROP has been shown to be correlated with taste sensitivity to a wide variety of other compounds, including those testing bitter, salty, sour and sweet (Fischer, R., and Griffin, F., 1964)". The discrepancy between this statement and the content of the quoted reference can easily be corrected if the word 'quinine' is substituted for 'PROP'. Taste thresholds for quinine follow a Gaussian distribution, whereas those for PROP, that is, 6-n-propylthiouracil, follow a bimodal distribution. Dr. Glanville, Dr. Kaplan and Mrs. F. Griffin also state that they have shown (*Nature*, 200, 343 (1963), seventh paragraph from the end, as well as *Recent Advances in Biological Psychiatry*, 7, 183 (Plenum Press, New York, 1965)), that subjects with low taste thresholds for quinine are also sensitive tasters of a wide variety of

chemically unrelated compounds—with the exception of hydrochloric acid, the taste threshold distribution of which follows a Gaussian curve.

## Announcements

THE sixteenth international Astronautical Congress will be held in Athens during September 12–18. Further information can be obtained from the Secretary, International Astronautical Federation, 250 Rue Saint-Jacques, Paris 5.

A SYMPOSIUM on "The Ecology of Soil Bacteria" will be held in the University of Liverpool during September 6–12. Further information can be obtained from Dr. T. R. G. Gray, the Hartley Botanical Laboratories, the University, Liverpool 3.

THE one hundred and second meeting of the British Pharmaceutical Conference will be held in Cardiff during September 6–10. Further information can be obtained from the Secretary, British Pharmaceutical Conference, 17 Bloomsbury Square, London, W.C.1.

A CONFERENCE on "Internal Friction in Solids", arranged by the Materials and Testing Group of the Institute of Physics and the Physical Society, will be held in the University of Manchester during September 7–9. Further information can be obtained from Dr. G. M. Leak, Department of Metallurgy, the University, Manchester 13.

A SYMPOSIUM on "Some Biological Systems at the Molecular Level", arranged by the Commission on Molecular Biophysics of the International Organization for Pure and Applied Biophysics, will be held in Naples during September 8–11. Further information can be obtained from Prof. R. C. Williams, Virus Laboratory, University of California, Berkeley, California 94720.

A CONFERENCE on "Fluid Logic and Amplification", organized by the British Hydromechanics Research Association and the Production and Industrial Administration Department of the College of Aeronautics, will be held at Cranfield during September 9–10. Further information can be obtained from the Information Office, British Hydromechanics Research Association, Cranfield, Bedford.

THE first international conference of the International Organization for Medical Physics will be held at Harrogate during September 8–10. The programme will include discussions on: physics in medicine and surgery; physics applied to physiology; physics in radiology. Further information can be obtained from the Secretary, United Kingdom National Committee for Medical Physics, 45–47 Little Britain, London, E.C.1.

A SYMPOSIUM on "Electromagnetic Distance Measurements" will be held at Oxford, under the aegis of the International Association of Geodesy at the invitation of the Royal Society, during September 5–11. The programme will include sessions on: microwave distance measurement systems; electro-optical distance measurement systems; application of masers and lasers to distance measurements; electromagnetic wave propagation questions; airborne and satellite-borne systems; electromagnetic measurements of short distances. Further information can be obtained from the Secretary, Electromagnetic Distance Measurements Symposium, Ordnance Survey, Chesham, Surrey.

CORRECTION. In the biographical note dealing with the appointment of Mr. W. J. Charnley as head of Weapons Department at the Royal Aircraft Establishment (*Nature*, 206, 1097; 1965), it is incorrectly stated that Mr. Charnley graduated at the University of London in 1940. Mr. Charnley in fact graduated at the University of Liverpool in 1942. Furthermore, he was awarded an M.Eng. in 1944 and not 1954 as stated.

## PLANT PHENOLICS INTO PHYTOCHEMISTRY

By DR. E. C. BATE-SMITH, C.B.E.

Low Temperature Research Station, Cambridge

## Origin and History of the Plant Phenolics Group

TWELVE years ago a meeting was held at Long Ashton Research Station, near Bristol, which proved to be the starting point of a highly rewarding adventure. This meeting on plant tannins was organized jointly by Long Ashton and the Low Temperature Research Station at Cambridge, and the invited guests were from other food research laboratories, from leather and forest product research laboratories, and from university departments of botany and chemistry, including those of the University of Bristol. It was here that 'phenolics' were christened and the foundation laid, although unwittingly, for the formation, five years later, of the Plant Phenolics Group.

It is interesting to recall why the Group met such an immediate and enthusiastic response. So far as plant physiology was concerned, the function of the phenolic constituents was unidentified and apparently unimportant. Lignification was an event taken more or less for granted, of concern only to the plant anatomist and the paper industry, tannins had no evident function and, together with many of the simple phenolic constituents, could most conveniently be regarded as waste products of organisms unprovided with excretory apparatus. The phenolases might perhaps be concerned with respiration, but could not be shown to play any such part in normal physiological processes. Only the anthocyanins of flowers and fruits could be allocated a role in fertilization and seed dispersal. Since there was no one in the world of botany to take an interest in the phenolic constituents of plants, the chemists set out to look after the field themselves.

A start had been made in 1947 in the application of paper chromatography to the anthocyanins and flavones of flower petals; but it was Dr. A. E. Bradfield, working for the Indian Tea Association in the laboratories of J. Lyons and Co., Ltd., and later at East Malling Research Station, who really set the wheels in motion. Making skilful use of partition chromatography, he separated a number of fractions from the tea tannins and showed them to be the 8-galloyl esters of catechin and galocatechin, then, using paper chromatography for the first time as an analytical tool in phenolic chemistry, he and I established the configuration of the diastereoisomers of the galocatechins and their galloyl esters. Although, unfortunately, he died before it came into being, it was his authority as a chemist which underpinned the phenolics group in its formative period. His work for the Indian Tea Association and his support of the Group were vigorously carried on by his successor, Dr. E. A. H. Roberts, who later became the second chairman of the Group.

The Plant Phenolics Group was broadly based to cater for the botanist and the chemist, for the university scientist and for the technologist in industry. The subject for discussion at the inaugural meeting at Cambridge, in June 1957, "The Oxidation of Plant Phenolics", was chosen to attract as numerous and representative an attendance as possible. The same objective governed the selection of subjects for discussion at subsequent annual general meetings, the *Proceedings* of which have nearly all been published.

In addition to these annual general meetings, two meetings a year were held on more narrowly based topics. The last of these, foreshadowing the widening of the field which had already been decided on, was a symposium on "The Comparative Biochemistry of the Leguminosae", a subject still largely phenolic in its content, but including also alkaloids, unusual amino-acids, seed proteins and carbohydrates.

## Evolution of a Phytochemical Group

The Plant Phenolics Group had no difficulty in finding attractive subject-matter for three meetings a year, even though the field is a restricted one. The question of an extension of the Group's activities had, however, always been in the minds of successive committees. It had been hoped that other limited subject-areas of phytochemistry might be similarly developed, so that in due course a 'super-group' might be formed co-ordinating the separate activities of a number of such associations. However, many members of the Group were interested in other kinds of plant constituents such as terpenes, alkaloids, carotenoids and amino-acids, and since there was no indication that the group would be trespassing on other people's ground if these were absorbed into its activities, a move was made two years ago to test the feelings of the members about expanding the Group to include the whole range of secondary plant constituents. Finally, at the annual general meeting in April, 1964, the Plant Phenolics Group voted itself into a new phase of existence as the Phytochemical Group.

There are many consequences of this expansion of activity. First, of course, the membership can be expected to increase and, secondly, the programme will inevitably become to some extent sectionalized. But one thing above all else the present Committee wishes to preserve is the comfortable informality of the Group's proceedings. This desire for informality is behind the choice of title; a group can be as formal or informal as it pleases.

There is also a deliberate intention in the choice of 'Phytochemical' as the descriptive element in the title, both a broader and a narrower intention than would be implied, for example, by 'Plant Chemical' or 'Plant Biochemical'. Perhaps the nearest one can get to a definition is that there is at all times an effort to understand the significance of the chemical constituents, especially the secondary constituents, in the life of the plant, and the effect they may have on the lives of man and animals. These objectives give point to the work of the chemist in isolating and characterizing new natural products, and fortify the plant physiologist with knowledge of the identity and possible function of these plant constituents.

There is one reason why the formation of a Phytochemical Group is especially timely, and that is the rapid growth of chemical taxonomy, or biochemical systematics. While much of the initiative for this outburst of activity has come from the chemical side botanists are equally prominent. One international conference has already been held, and its *Proceedings* have been published<sup>1</sup>. An outcome of this conference has been the proposed formation of a Chemical Taxonomy Commission of the Organic Chemistry Section of International Union of Pure and Applied Chemistry, and the creation of a formal link between this and a recently formed committee of the International Association of Plant Taxonomists.

This comes at a time when there is much searching—and some burning—of heart among plant taxonomists themselves, and indeed among classifiers and systematizers of knowledge generally. It can be foreseen that chemical characters will be needed, although reluctantly admitted, along with anatomical, cytological and palynological characters, as adjuncts to the characters of classical taxonomy, which seem to be reaching the limits of their unaided application to problems of classification. All this interest will promote activity among the members of the Phytochemical Group and will be strongly reflected in its programme. Indeed, the subject of the first annual general meeting of the new Group, which was held in

Cambridge in April, 1965, was a three-day symposium on "Comparative Phytochemistry", a report of which is given in the following article.

Much of the knowledge of the chemistry of plants has been gained by the search for pharmacologically active substances, so that the applications of phytochemistry in the pharmaceutical field can also be expected to be prominently featured in the Group's programme. But there is a field of at least equal interest and importance in the occurrence of physiologically active compounds in actual or potential foods and feeding-stuffs. Outstanding examples of these are the oestrogens in leguminous crop plants and the recent discovery of aflatoxin in spoiled groundnuts. Besides these harmful constituents there is a growing need for chemical knowledge—and, in gas chromatography, the means of obtaining it—of the nature of aroma substances in foods. It is to these constituents that so much of the attractiveness, or unattractiveness, of food is due. Both in the breeding and growing of the fresh foods, and in the preservation and enhancement of fresh quality the demand is for an understanding of the nature of the aroma substances. Just as our knowledge of the pigments has advanced during the past few years so our knowledge of the 'aromatics' can be expected to grow during the coming years, and these aroma substances cover

a far wider range than the comparatively few kinds of substances to which the plant pigments are confined. The usefulness of this knowledge can be expected to extend, and is, indeed, already extending, to the palatability of animal feeding-stuffs, now that intensive feeding methods are beginning to assume so much importance in stock raising and dairy farming.

While some regard must be given to sectional interests in the activities of the Group, its objectives will be much better promoted by emphasizing the more general aspects of phytochemistry. With the increasing complexity and specialization both of academic chemistry and the various branches of industry there is a tendency for departmentation and segregation to increase. It will be one of the great advantages of meetings of the Group that departmental barriers can be broken down in the discussion of such topics as biosynthesis and chemical taxonomy, subjects which not only embrace the whole range of natural products, but which also possess an exciting and rewarding intellectual content. These are satisfying activities for the increasing number of those for whom chemistry for chemistry's sake and botany for botany's sake are not enough.

<sup>1</sup> *Chemical Taxonomy*, edit. by Swain, T. (Academic Press, 1964).

## COMPARATIVE PHYTOCHEMISTRY

By DR. J. B. HARBORNE

John Innes Institute, Bayfordbury, Hertford

**A**N international symposium on comparative aspects of plant chemistry, organized by the Phytochemical Group with the financial assistance of the Scientific Affairs Division of NATO, was held in Cambridge during March 30–April 1. The main theme of the meeting was the taxonomic implication of the natural distribution of the various groups of plant constituents, but their biogenesis, evolution and general biochemistry were also discussed. The taxonomist's view of phytochemistry was given by Prof. V. H. Heywood (Liverpool) in the introductory lecture. He dealt with the problems of incorporating chemical data into classification and showed why it was impossible to recommend the phytochemist to use one rather than another of the various plant classifications that are available. He pointed out that a number of systems will always be needed to fulfil different objectives.

In a second introductory lecture, Prof. C. R. Mentzer (Paris) expounded his well-known biogenetic classification of plant constituents, in which substances are placed together according to their biogenetic origin rather than on the basis of chemical complexity as in Beilstein.

The first main session, under the chairmanship of Prof. L. Fowden, was devoted to the distribution of nitrogenous compounds. Dr. E. A. Bell (London) described the distribution patterns of non-protein amino-acids he had obtained using paper electrophoresis of legume seed extracts. These patterns, he said, could be used to divide each of the genera *Lathyrus* and *Vicia* into several distinctive biochemical groups. He pointed out that comparisons of biosynthetic pathways were probably more valuable with unusual amino-acids than considerations of the distribution of single compounds. Prof. R. Hegnauer (Leiden), in considering the taxonomic significance of the comparative chemistry of the alkaloids, found many examples of parallelism and diversification. One of the conspicuous successes of chemical taxonomy has been the discovery that betacyanins and betaxanthins are restricted to one order of plants, the Centrosepermae, and the final paper in this session, given by Dr. T. J. Mabry (Texas), dealt with these purple and yellow alkaloidal pigments.

After describing the chemistry of these substances, Dr. Mabry considered the various arrangements that have been proposed for the betacyanin-containing families and showed that his results definitely discounted the Hutchinson system in this context.

The second session was devoted to phenolic constituents and included a consideration of hydroxyquinones (Dr. O. Mathis, Strasbourg), dihydrochalcones (A. H. Williams, Bristol), glycoflavones (Prof. H. Wagner, Munich) and flavonoid pigments (Dr. J. B. Harborne, John Innes Institute). It was clear from these papers that although phenolics are among the most promising of taxonomic markers, they have not as yet made much contribution to plant systematics. For example, the dianthrone hypericin, as Dr. Mathis found, is characteristic of the genus *Hypericum*, but it only occurs in about half of the 300 species examined. One difficulty in evaluating the results of surveys is the occurrence of 'chemical races' within a single species. A dramatic example of this phenomenon was uncovered by A. H. Williams, who found that some samples of the dihydrochalcone-containing *Smilax glycyphylla* either lacked phenols altogether or contained the xanthone, mangiferin, instead. Glycoflavones are more widely occurring than dihydrochalcones but little is known of their detailed distribution at the generic level. One of the main difficulties with glycoflavones is distinguishing them from the more common flavone O-glycosides, and Prof. Wagner dealt mainly with this aspect of their phytochemistry in his lecture. Because of their importance as petal pigments, the flavonoids are very interesting from an evolutionary point of view, and Dr. Harborne, therefore, sought correlations between flavonoid structures and evolutionary advancement. He also described some recent surveys in the Gesneriaceae and Plumbaginaceae, in which novel correlations have been found between anthocyanin distribution and pollen or leaf morphology.

The third session, under the chairmanship of Prof. H. Erdtman (Stockholm), dealt with hydrocarbons and their derivations. Dr. G. Eglinton (Glasgow) said that the alkane distributions so far studied indicated a reasonable

species constancy, but that the chemotaxonomic use of alkane patterns had so far met with only moderate success. The acetylenic compounds also present taxonomic difficulties, occurring as they do in such disparate groups as the fungi Polyporaceae and the highly advanced Compositae. Dr. J. D. Bu'Lock (Manchester) pointed out that some of the anomalous aspects of acetylene distribution within the Compositae could be explained by considering biosynthetic pathways, so that more knowledge of biosynthesis is vital in this series. Dr. G. Weissman (Hamburg), in considering the occurrence of terpenoids in plants, also found that biogenetic relationships were of prime importance in understanding distribution patterns. In the final lecture of this session, Prof. T. W. Goodwin (Aberystwyth) mentioned that carotenoids were of considerable systematic importance in lower plants, but were of little significance in the angiosperms since all green leaves contain the same set of major carotenoids. Fruit carotenoids do, however, show interesting variations as they can be divided into four categories, but the interest here is mainly their biosynthetic origin rather than their systematic distribution.

The first paper in the fourth and final session of the symposium was given by Dr. E. Percival (London). In surveying the vast and complex field of polysaccharide

chemistry, she pointed especially to similarities and differences in structure between algal and higher plant acidic polysaccharides. She concluded that generic and species differences will only emerge when the fine details of these macromolecules have been elucidated. Prof. A. J. Kjaer (Copenhagen) also had a large area to cover, since he dealt with sulphur-containing amino-acids and alkaloids, thiols, simple sulphides and polysulphides. His main theme, however, was the distribution of the isothiocyanate-producing glucosides, which show a number of interesting correlations with taxonomy. In a joint paper, Dr. T. Swain (Cambridge) dealt with the chemistry and Dr. E. C. Bate-Smith (Cambridge) the distribution of a class of substances including aucubin and asperuloside, now known collectively as iridoids. It was pleasing to find that their distribution in families in the order Tubiflorae fits in particularly well with the recently published twelfth edition of Engler's *Syllabus of Plant Families*. Finally, Dr. Ruijgrok (Leiden) outlined the distribution of the lactone ranunculin in the Ranunculaceae and correlated its occurrence with those of cyanogenetic compounds, which are also present in this family. This talk concluded a very successful meeting, in which both chemists and taxonomists contributed to discussions of the many papers. It is planned to publish the proceedings in full later this year.

## HOT-LABORATORY WORKING METHODS

AN international symposium on working methods in high-activity hot laboratories, organized by the European Nuclear Energy Agency in collaboration with Euratom, was held at the French Centre d'Etudes Nucléaires in Grenoble during June 14-18. The symposium provided a forum for discussion, by some 130 experts from hot laboratories in the nuclear research centres of 15 European and American countries of OECD and Euratom, of specialized methods and equipment for handling radioactive materials with activities greater than 1,000 curies.

The main purpose of hot laboratories, of course, is to permit experimental work on these highly radioactive materials without endangering the personnel carrying out the work. Although in the past such experiments have usually been related to research and development programmes, there is now a growing amount of purely routine work—such as regular analysis of irradiated fuel samples to determine burn-up—for which comparatively simple standardized equipment could often replace the complex and unnecessarily flexible apparatus of the pure research laboratory.

Equipment for both purposes was discussed at Grenoble and it became clear, even for complex research purposes, that laboratory experts preferred simple and economical rather than highly sophisticated equipment provided only that it would do its job in a safe and efficient manner.

Throughout the symposium there was repeated emphasis on the need for designers of hot-laboratory facilities to work more closely with the users, so avoiding the need to make an installation unnecessarily flexible through lack of foreknowledge of its purpose. Improved liaison was also often possible between the hot-laboratory operator and his "client"—the reactor operator or research engineer—so that the one could know as accurately as possible what the other wanted him to do. The earlier this liaison took place, the less complicated the hot-laboratory equipment might well be.

On the other hand, a too-rigid limitation of use could lead to considerable expense when, as was often the case, advancing technology required modifications to what had become standard test procedures. Economics and flexibility were in fact often in opposition, and an efficient compromise was not always easy to find.

Although the symposium was concerned with hot laboratories for all purposes, most of the papers presented dealt with installations for work on irradiated fuels, and several stressed the problems to be expected from the advancement of fast reactors. Monsieur André Valentin (Commissariat à l'Energie Atomique, Fontenay-aux-Roses, France), in summing up the situation, mentioned that such reactors would undoubtedly operate to very high fuel burn-ups—for example, it was generally thought that plutonium carbide fuels would not be interesting unless taken to burn-ups greater than 50,000 MW days/tonne. This was likely to lead to considerable and important developments in hot-laboratory methods.

Mr. K. R. Ferguson (Argonne National Laboratory), in reviewing present techniques in the United States, stressed the value of experience in building up these techniques. Such experience enabled consistently reliable results to be obtained from comparatively simple apparatus having the highest standards of safety and protection, while less-experienced operators would feel impelled to use more complex equipment which was certainly less economical and could also be less reliable.

A discussion of various types of 'enclosure' directed attention to the advantages of incorporating all or most of the remote handling operations of a particular process within a single complex of interconnected containments. By thus reducing the frequency of transfer across the containment barrier, both containment reliability and operating efficiency could be greatly increased. Such cell complexes are to be used at the Fuel Recycle Pilot Plant at the Hanford Laboratories, the Oak Ridge Transuranium Laboratory, the Oak Ridge Thorium-uranium Recycle Facility, and the Alpha-Gamma Metallurgical Hot Cell at Argonne.

Concerning the use of 'boxes' within hot cells, it was generally agreed that these were necessary for handling materials above a certain activity (for example, above a total alpha count of  $10^{11}$ /min was suggested) to avoid excessive time loss in decontamination and to provide added assurance of safety. Boxes were also needed to avoid cross-contamination between different materials handled simultaneously in the same laboratory.

There was some discussion on methods and equipment for both individual and general dosimetry, and here again

it appeared that there was scope for closer liaison between the two specializations concerned, namely the radio-chemical technology of the hot laboratory and the physico-biological technology of radio-protection. There was at least one suggestion that this matter might be the subject of a future symposium.

It was perhaps not surprising that on most matters considered at Grenoble, the conclusions of the experts from the various countries represented were similar. Indeed in many fields it was clear that standard methods were beginning to be adopted (particularly for non-destructive

testing) and that this was leading to the adoption of standardized items of equipment in all laboratories. Participants generally welcomed this trend which doubtless owes its origins to previous international discussions which, if on a less ambitious scale, were none the less the forerunners of the Grenoble Symposium.

The *Proceedings* of the Symposium, including all papers and discussions as well as a directory of high-activity hot laboratories in operation in OECD countries, will be published by ENEA towards the end of September.

## MENDEL MEMORIAL BUILDING, HYNČICE

ON June 13, the birthplace of Gregor Mendel at Hynčice, Czechoslovakia, was officially opened to the public and a memorial plaque unveiled to celebrate the occasion.

The house, built by Mendel's father on the site of a former wooden building, has been reconstructed, thanks to the efforts of the Regional Department for the Preservation of Historical Monuments in Ostrava, the District National Council, and the District Museum in Nový Jičín. On the ground floor, the Moravian Museum of Brno has restored the former kitchen and the room where Mendel was born.

The arrangement of the memorial building was, to a great extent, determined by the rooms available. This necessitated dividing them into two parts, representing, on one hand, Mendel's life and, on the other, his scientific activities.

In the first part, Mendel's birth certificate is displayed in the room where he was born in 1822. Other exhibits there record his genealogy, family background, and details of the schools where he obtained his basic education. There are also photographs and documents of the period, testifying to Mendel's entry into the Monastery of Old Brno, his teaching activities at the Brno Secondary School, and finally his election as Abbot in 1868. The final exhibits in this section include the obituary notice issued by the Monastery on the day of his death, and the photograph of the Monastery vault in the Central Cemetery in Brno, where he gained his final resting place.

The second part, which is aimed at acquainting the visitor with Mendel's work and its significance, particularly stresses his interest in natural science. It was this interest which led him, after his theological studies had been completed, to study at the University of Vienna.

Later he returned to Brno where for many years he performed his experiments on the heredity of peas. It was these, now classical experiments, which led to the formulation of his theory of dominant and recessive characters and its publication in 1865. His theory, however, was not recognized until it was publicized by de Vries, Correns and Tschermak at the beginning of the present century. The final documents exhibited in this section indicate the great use which scientific research workers throughout the world have made of Mendel's work.

The official opening of Mendel's birthplace aroused considerable interest among the general public, and at the ceremony Dr. V. Orel, head of the Gregor Mendel Department of Genetics in the Moravian Museum in Brno, gave an inaugural address in which he briefly outlined Mendel's life and explained the significance of his work. He also recalled Mendel's close ties with his family and his native village.

The opening of this memorial building gave Hynčice the chance to inaugurate the official celebrations of the centenary of the publication of Mendel's classic paper, and in this way of paying honour to its most famous son.

LUDMILA MARVANOVÁ

## POSITIONS OF THREE COSMIC X-RAY SOURCES IN SCORPIO AND SAGITTARIUS

By G. CLARK, G. GARMIRE, M. ODA\* and M. WADA†

Laboratory for Nuclear Science and Department of Physics, Massachusetts Institute of Technology

AND

R. GIACCONI, H. GURSKY and J. R. WATERS

American Science and Engineering, Inc.

WE have determined the positions of three cosmic X-ray sources in the constellations of Scorpio and Sagittarius within uncertainty areas of 1.2–3 square degrees. Positions for these sources were reported earlier by us at the Austin Conference on Relativistic Astrophysics on the basis of a preliminary analysis of the same data<sup>1</sup>. One of these sources is ScoX-1, which was first detected by Giacconi *et al.* in 1962 (ref. 2). (Our designations specify the constellation and the order of discovery, for example, ScoX-2 for second X-ray source in Scorpio.)

The other two, SgrX-1 and ScoX-2, lie near the galactic plane in the complex of sources the existence of which was reported in a previous publication<sup>2</sup>. We have also located a probable fourth source to within 1° of a segment of a great circle that is almost parallel to and about 4° below the galactic equator. The Kepler supernova remnant SN1604 was scanned and no evidence of an X-ray source at its position was found.

We obtained the data with a rocket that was launched from White Sands, New Mexico, on October 26, 1964, at a sidereal time of 20h 20m, and reached an apogee of 224 km. Above the atmosphere the rocket spun around

\* On leave from the University of Tokyo.

† On leave from the Institute of Physical and Chemical Research, Tokyo.

its long axis with an almost constant angular velocity of approximately 808 deg/sec. The spin axis precessed with an angular velocity of 5.51 deg/sec around a circular cone the apex angle and spatial orientation of which did not vary by more than  $0.3^\circ$  during the 260 sec when useful X-ray data were obtained.

The effects of the rocket motion on the observations are most easily visualized in the rocket frame of reference which we define to be a co-ordinate system fixed in the rocket with its  $z$ -axis parallel to the spin axis. During each spin any given point on the celestial sphere moved through  $360^\circ$  of azimuth in the rocket frame at an almost constant angle of elevation with respect to the rocket equator. In addition, the precession caused the elevation angle of an object to vary periodically with an amplitude equal to one-half of the apex angle of the precession cone. Thus an object was observed repeatedly in successive spins whenever it moved within the elevation range of a given detector's field of view.

In describing our analysis, we shall refer to the precession frame of reference which we define to be a co-ordinate system the  $z$ -axis of which is parallel to the axis of the precession cone, and the  $x$ -axis of which is in the direction of the vector product  $\hat{s}_c \times \hat{s}_p$ , where  $\hat{s}_c$  and  $\hat{s}_p$  are unit vectors parallel to the  $z$ -axes of the celestial and precession co-ordinate systems, respectively. We define the spin azimuth of a direction to be its azimuthal angle measured around the spin axis from the direction of  $\hat{s}_p \times \hat{s}_c$ , where  $\hat{s}_c$  is a unit vector in the direction of the spin axis. We define the bearing of a direction to be the sum of its spin azimuth and the precession azimuth of the spin axis. During one complete precession cycle the spin azimuth of a given direction fixed in space decreases non-uniformly by  $360^\circ$ . In the same period the precession azimuth of the spin axis increases uniformly by  $360^\circ$ . Therefore, the bearing of a fixed direction varies about a mean value which, as one can easily see, differs by  $90^\circ$  from the azimuth of the fixed direction in the precession frame. The amplitude of this variation is determined by the angle of the precession cone and the elevation of the direction with respect to the precession equator.

The rocket carried a variety of instruments, among which were several X-ray detectors and two star sensors. The data consisted essentially of the occurrence times of pulses from these detectors and sensors. Four of the X-ray detectors were banks of Geiger tubes, each having sensitive areas of 70 cm<sup>2</sup>, beryllium windows 8 mg cm<sup>-2</sup> thick, and argon fillings giving a gas thickness of 5.4 mg cm<sup>-2</sup>. Three of the banks had slit collimators that gave rectangular fields of view with full widths of  $3.0^\circ$  in the narrow dimension, and  $30^\circ$  (detectors GH0 and GH20) or  $40^\circ$  (detector GV10) in the wide dimension. The narrow dimensions of detectors GH0 and GH20 were perpendicular to the rocket equator, while that of detector GV10 was parallel. The fourth bank, detector GMC0, had a modulation collimator<sup>4</sup> the response function of which, in the direction perpendicular to the rocket equator, was a saw-tooth function with maxima at rocket elevation angles given by the formula  $1.4^\circ \pm \arctan(0.0417n)$ , where  $n$  is an integer. In the direction parallel to the rocket equator the response function of detector GMC0 was triangular with a base width of  $15^\circ$ . The star sensors, SS0 and SS30, had effective fields of view of  $1.0^\circ \times 5.2^\circ$ , with their long dimensions perpendicular to the rocket equator. In our detector designations the number following the letter code specifies the nominal elevation in degrees of the centre of its field of view above the rocket equator. We determined the actual orientations of the detectors and star sensors in the rocket frame of reference to accuracies of  $\pm 0.3^\circ$  in elevation and azimuth by optical measurements on the ground before and after the flight.

We solved the problem of determining the orientation of the rocket in the celestial frame of reference at any

given instant in the following way. We first made use of the fact that ScoX-1 was within the elevation range of the modulation collimator throughout the precession cycle. We could therefore determine the amplitude of its variation in elevation from the observed modulation caused by the motion of ScoX-1 back and forth over the saw-tooth response function. This amplitude, which is equal to the full apex angle of the precession cone, was found to be  $5.1 \pm 0.1^\circ$ . (This angle could also be determined from the star sensor data, though not with as high accuracy as from the modulation collimator data.) From the relative times of the signals from the star sensor SS0, we identified seven stars between the second and fourth magnitude as the sources of the signals. We then determined the orientation of the precession cone axis and the phase of the precession motion which minimized the mean square difference between the predicted and observed times when these seven stars entered and left the elevation range of the star sensor during the precession cycle. We found that the precession axis lay in the direction with right ascension  $302.2^\circ \pm 0.5^\circ$  and declination  $38.2^\circ \pm 0.3^\circ$ . From these data we could calculate the celestial orientation of the spin axis at any given instant. Analysis of the nearly periodic pulses from SS0 produced by various stars repeatedly crossing the field of view showed that the spin frequency increased approximately linearly with time by about 0.2 per cent during the useful period of the flight. Thus the bearing of the axis of any given detector, which for constant precession and spin frequencies would be a linear function of time, could be expressed by a quadratic function of time. The average deviation between the computed and the actual bearing was less than  $\pm 0.5^\circ$  over the useful observation period.

To determine the relative bearings of the X-ray sources and reference stars, we plotted the numbers of counts per bearing interval from each of the detectors as a function of the bearing of the detector's axis, reduced modulo  $360^\circ$ . The data accumulated over four precession periods are shown in Fig. 1. The main peak of the distribution for detector GV10 in Fig. 1a is due to ScoX-1. The difference between its average bearing and that of the star  $\beta$ -Cetus, observed by the star sensor SS0, is  $239.8^\circ \pm 0.3^\circ$ . A segment of the great circle through the precession axis direction with this azimuth relative to  $\beta$ -Cetus is marked A in Fig. 3. We conclude that ScoX-1 lies within  $0.3^\circ$  of this segment.

The second, broader peak in Fig. 1a is due to the complex of sources near the galactic centre. From the fact that the ratio of the amplitude to the area of the peak is less than one-half times that of the ScoX-1 peak we conclude that it contains more than two sources. Arcs B and C in Fig. 3 are loci of positions the average bearings of which are equal to the values marked B and C in Fig. 1a. They are segments of great circles drawn through the precession axis, and they bound the region within which these sources lie. The Kepler's supernova remnant SN1604 lies  $2^\circ$  outside this region, and the radio source SgrA at the galactic centre is just barely within it. The separate peak, the average bearing of which is marked D in Fig. 1a, is  $3.5^\circ$  above the background. It is probably caused by a separate source that lies somewhere along the great circle segment marked D in Fig. 3.

The bearing distribution for the GMC0 detector is shown in Fig. 1b. It has separate peaks due to ScoX-1 and the galactic centre complex, but it has a low angular resolution and does not improve the bearing determinations already made with the GV10 data.

Figs. 1c and 1d show the bearing distributions for the two detectors GH0 and GH20 the fields of view of which were narrow slits parallel to the rocket equator. Both show the presence of sources which are a part of the complex between circles B and C, and which lie within the two 8-degree wide elevation bands scanned by the detectors during the precession cycle. These bands are bounded by the small circles marked GH0 and GH20 in

Table 1. POSITIONS (EPOCH 1950.0) OF THREE X-RAY SOURCES  
The preliminary values of the position co-ordinates given earlier in ref. 1 are shown in parentheses

Source	Right ascension	Declination
ScoX-1	16h 18m or 16h 19m	-15.6° -14.0
ScoX-2	16h 50m	-30.6° (-41°)
SgrX-1	17h 44m (17h 57m)	-23.2° (-24°)

Fig. 3. It is apparent from the absence of a peak at the bearing of ScoX-1 in either distribution that ScoX-1 does not lie within either of these bands.

To obtain more precise information about the elevation of a source with respect to the precession equator we examined the precession variation in the rates of counts in an appropriate bearing interval round the average bearing of the source. At any fixed bearing the precession elevation of a detector axis varied with an amplitude equal to one-half the apex angle of the precession cone. If a source lay in the region scanned, this variation in elevation caused a variation in the X-ray counting rates that could be fitted to the known response curve of the detector by a proper choice of the elevation of the source with respect to the precession equator. Fig. 2a shows the results for the GV10 detector. The abscissa is the relative elevation which we define to be the precession elevation of the detector axis at the centre of the indicated bearing interval minus its fixed rocket elevation. The fact that the counting rate was a maximum at the maximum relative elevation of the spin axis shows that ScoX-1 is above the maximum precession elevation of the GMCO axis, which limit is indicated by the dashed line that crosses the bearing circle A. On the other hand, ScoX-1 cannot lie above the band bounded by the GH20 lines because the observed elevation variation is too small. Therefore, ScoX-1 must lie between the dashed line and the lower boundary of the GH20 band.

To refine the elevation determination of ScoX-1 we used the GMCO data the elevation variation of which is

Fig. 1. Bearing distributions of the counts from the four detectors in the vicinity of ScoX-1 and the galactic centre complex. The full widths of the fields of view are indicated under the label of each detector. The background levels are indicated by the dashed lines

Fig. 2. Variation of the counting rates with the relative elevation of the detector axis at the midpoint of the indicated bearing interval. The background levels are indicated by the dashed lines

shown in Fig. 2b. From the completeness of the modulation, as well as that of the modulation observed in a previous experiment with a similar but higher resolution collimator, it was possible to conclude that the angular diameter of ScoX-1 is less than 7 arc min (ref. 5). One sees here that ScoX-1 lies on one of the maxima of the response function when the precession elevation of the GMCO axis is  $-2.3^\circ$ ,  $-0.2^\circ$  or  $+1.8^\circ$ . The solid lines crossing the bearing circle A show the positions of the two maxima which fall between the limits previously determined. We are not able to choose between the two intersections on the basis of the data from this experiment. The boxes around each of the two intersections are  $0.6^\circ$  wide by  $1.0^\circ$  long, and they indicate the estimated errors in the bearing and elevation determinations, respectively.

Figs. 2c and 2d show the elevation variation of the counts from the sources observed by the GH0 and GH20 detectors. In both cases the sources appear to lie about  $0.3^\circ$  below the midpoint of the elevation scan as indicated by the line crossing the bearing circles D and E. We determined these latter bearing circles using only the data from the parts of the precession cycle when the sources gave the highest counting rates. As before, the boxes around each intersection indicate the estimated errors in the position determinations.

The two alternative positions we find for ScoX-1 are both within the uncertainty circle of  $2^\circ$  radius around the position published by the NRL group<sup>4</sup>. The lower of the two is within  $0.5^\circ$  of the position given by Fisher *et al.*<sup>1</sup>.

Fig. 2. Mercator projection of the celestial sphere in the region of the galactic centre. The cross-hatched areas show the locations of the sources as determined in this experiment. The small circles labelled GV10, GH0, etc., are the extreme boundaries of the regions scanned by the corresponding detectors.

*Sgr X-1* is  $5^\circ$  away from the Kepler supernova remnant *SN1604*. The absence of a significant peak at the average bearing of *SN1604* in the *GV10* data in Fig. 1a shows that any X-ray emission from this remnant must be several times smaller than that of the nearby sources. Therefore, our observations do not support the identifica-

tion of an X-ray source with *SN1604*, as suggested by the *NRL* group<sup>6</sup> on the basis of data obtained with an instrument of lesser angular resolution.

*Sco X-2* lies more than  $5^\circ$  away from the position of the nearest source reported by the *NRL* group<sup>6</sup>.

Two of the circular arcs along which Fisher *et al.*<sup>7</sup> have located sources pass within  $1^\circ$  of our locations for *Sgr X-1* and *Sco X-2*, respectively.

Finally, we note that there is a striking lack of symmetry with respect to the galactic centre in the distribution of the general X-ray emission from this region. The centre line of the emission region between lines *B* and *C* in Fig. 3 passes the galactic centre at a galactic latitude of  $b_{\text{ll}} = +2.5$ . It is also apparent that the radio centre of the galaxy, *Sgr A*, is at most a weak X-ray source compared with the other sources nearby.

This work was supported in part by the National Aeronautics and Space Administration under contracts *NASA*-898 and *NSG*-386 and in part by the U.S. Atomic Energy Commission under contract *AT* (30-1) 2098.

## A HIGH-SENSITIVITY SURVEY OF M31 AND SURROUNDINGS AT 1,415 MEGACYCLES PER SEC

By PROF. J. D. KRAUS and R. S. DIXON  
Radio Observatory, Ohio State University, Columbus

MAPS of the Andromeda and Perseus regions made at 600 and 1,415 Mc/s with the Ohio State University 260-ft. radio telescope have recently been published<sup>1,2</sup>. The telescope data output for these maps was recorded in analogue form (pen and paper chart) and all data were processed manually. The observations were completed in January 1964. By September 1964 a new stepped-amplitude twin-feed horn<sup>3</sup> and digital output had been installed for the 1,415 Mc/s receiver and a new survey of the *M31* region lasting four months was begun at this frequency. Using a liquid-nitrogen refrigerated parametric amplifier<sup>4</sup> and repeated scans a sensitivity (root mean square noise temperature) of  $0.01^\circ$  K was achieved with all data reduction done on the University's IBM 7094 computer. With this sensitivity and method of data processing, *M31* is resolved into a number of sources, one of which is close to the optical nucleus. Much detail is also brought out in surrounding areas that was not apparent on the earlier map. The region surveyed extends between right ascensions of 23h 30m to 02h 00m and north declinations of  $39^\circ 10'$  to  $43^\circ 10'$ . The antenna beam-widths at half power are  $13'$  in right ascension by  $38'$  in declination.

The results of the new observations are illustrated by the 17 profiles in Fig. 1 as plotted by the computer. The profiles are at declination intervals of  $15'$ . Each profile as plotted is the average of no less than four drift scans taken on different days except for one profile which is the average of three scans. A total of 72 scans is involved. A digital integration time of 10 sidereal sec was used so that more than 60,000 basic data points are involved in the 17 profiles. With additional scans at the central

declination ( $41^\circ 10'$ ) a profile involving the average of eleven scans was also made. This profile shows little difference as compared to the four-scan central profile in Fig. 1 even with respect to small details, indicating that with four scans the results are close to the resolution limit of the telescope. This means that a further increase in the telescope sensitivity would reveal no more significant detail at this frequency although the same results could be obtained with fewer scans.

The galaxy *M31* is evident as the extended object near the centre of Fig. 1 and appears to be resolved into as many as ten distinct radio features. A number of other prominent objects appear elsewhere in the figure as peaks on several adjacent profiles. (A point source should appear on three or four adjacent profiles and should trace the antenna pattern in right ascension with a time between half-power points of 53 sec.) Two sources in the third Cambridge list (3C13 and 3C54) are apparent in Fig. 1 although their centres are beyond the region surveyed. About twenty Ohio list *A* (O*A*) sources tabulated in the earlier survey are evident. A like number of additional sources are also apparent. These have been given new O*A* numbers and are listed in Table 1. The new sources are: O*A* 5, 16-1, 17, 23, 25, 27, 29, 35-1, 35-2, 35-3, 35-4, 35-5, 35-6, 35-7, 35-8, 35-9, 38-1, 39, 43, 53, and 61. Source O*A* 53 is an extended object which surrounds O*A* 52 and 54. (Sources are listed in Table 1 only for the right ascensions of Fig. 3.)

Fig. 2 is a contour map of the central region of Fig. 1 showing *M31* and its immediate surroundings. The contour interval is  $0.025^\circ$  K antenna temperature referred to as an arbitrary zero-level. The contours were drawn

manually on a map printed by the computer with each contour step indicated by a single digit. The contours outlining the emission from the galaxy show marked asymmetry. In both directions from the nucleus along the major axis the emission conforms to the axis but beyond swings away into narrow north and south spurs. The ten radio features associated with M31 are designated O436 and O435.1 through O435.9. The source O435.3 is less than 3' from the optical nucleus. Taking the distance of M31 as 2 million light years and assuming that this source is in the plane of the galaxy, it would be less than 2 kiloparsecs from the nucleus. Although the sources O436 and O435.6 may be background objects, their location in the north and south spurs gives some probability to their being associated with the galaxy. There is no indication of emission from NGC205 and none is apparent from M32, but the closeness of O435.3 makes this somewhat inconclusive. The fact that several sources, such as O435.4, O435.7, O435.8, rise only one contour-interval above the surroundings gives them only a low probability of reality. Sources O433, 35.2, 35.5, 36, 37, 38 and 39 appear at or close to peaks in MacLeod's map<sup>4</sup>, while O435.6, O437 and 38 are in the list of Scott, Ryle and Hewish<sup>5</sup>. Besides the much greater detail in Fig. 2 as compared with the earlier map<sup>1</sup>, the most noticeable difference is the absence of the spurs preceding and following M31 along its minor axis. The spurs may be real features but do not appear in Fig. 2 because the computer programme for removing long-term drift tended to discriminate against weak objects extended in an east-west direction.

Fig. 3 is a partial contour map of a larger part of the region of Fig. 1, in which a few selected contours are shown to indicate the locations of the principal sources with their OA or 3C designations. Of particular interest are the two clusters of sources about 30 min preceding and following M31 and the cluster to the south. The preceding cluster consists of O414, 16, 16.1, 17 and 18, and the following cluster of O442, 45, 46, 50, 52 and 54. The cluster to the south consists of O425, 26, 28, 29, 3013, O436, 37, 38 and 38.1. In the discussion of the earlier map the question was raised as to the possible relation of the preceding and following clusters with M31 (ref. 1). To these might also be added the cluster to the south. Thus, might some of the sources in these clusters be material ejected from the nucleus of M31 at some earlier epoch? There is an apparent north-south elongation of some of the sources in the preceding and following clusters and a marked beam broadening (east-west elongation) of some of the sources in the south cluster. The preceding and following clusters are at

opposite ends of an axis through M31. Circles centred on the nucleus of M31 and drawn through the members of these clusters, as shown by the dashed lines in Fig. 3, have a relatively uniform spacing. We offer the conjecture that some of the sources in these clusters may be associated with the wave crests of the shock-front of material ejected from M31 in a prior epoch and further that some of the sources in the south cluster may be at a comparable distance but in a direction from M31 more nearly along our line of sight. On the other hand, the cluster associations may be entirely a coincidence and the sources unrelated to M31. Further investigation is needed to decide between these possibilities.

Scott, Ryle and Hewish<sup>5</sup> list thirteen sources in the area of Fig. 3. Of these, twelve correspond to O45, 8, 16, 18, 24, 35.6, 37, 38, 45, 50, 54 and 59. Omitting one source which is complex, the systematic difference in

Fig. 1. Oblique view of M31 region as shown by high-sensitivity profiles made with Ohio State University 260-ft. radio telescope at 1,415 Mc/s. The sensitivity is 0.01° K with the strongest sources having an antenna temperature of less than 0.4° K. The centres of 3013 and 54 are beyond the declination limits of the survey but appear owing to their proximity. The same is true for the sources O4 24, 26 and 57.

## RE-SURVEY OF HURRICANE EFFECTS ON THE BRITISH HONDURAS REEFS AND CAYS

By D. R. STODDART

Department of Geography, University of Cambridge

CONSIDERABLE attention has been directed in recent years to the morphological and vegetational effects of catastrophic storms on the coastal features of high islands, such as Mauritius<sup>1,2</sup> and Guam<sup>3</sup>, and of atolls, particularly

Jaluit Atoll, Marshall Islands<sup>4,5</sup>, and Ulithi Atoll, Caroline Islands<sup>6</sup>. Most of these surveys were carried out shortly after the occurrence of major storms, and recorded immediate effects by comparison with pre-storm conditions.

On October 30–31, 1961, Hurricane *Hattie* crossed the atoll and barrier reefs of the British Honduras coast, causing major damage to reefs and islands shortly after a complete survey of island physiography and vegetation<sup>1</sup>. This made possible the detailed analysis of hurricane-induced changes during an expedition three months after the storm<sup>2,3</sup>. While the immediate effects of major storms is thus well documented, less is known about the long-term stability of hurricane-induced changes, and hence of the significance of such storms in the development of the surface features of coral reefs and islands. At Jaluit Atoll, the storm effects were re-surveyed three years after Typhoon *Ophelia*, when Blumenstock, Fosberg and Johnson<sup>4</sup> reported considerable changes in topography and vegetation during that period. During March–April 1965 a small expedition revisited the British Honduras reefs to collect data on reef and island changes in the 3½-year period since the immediate post-hurricane survey, in order to assess the long-term role of tropical storms in the evolution of reefs and reef islands. This report briefly notes the major conclusions of this re-survey, which may be compared with those of Blumenstock, Fosberg and Johnson at Jaluit Atoll<sup>4</sup>.

#### Nature of Immediate Hurricane Effects

The British Honduras coast is fringed by a 180-mile long barrier reef and coastal lagoon with three atolls (Turneffe Islands, Lighthouse Reef and Glover's Reef) to seaward. The reef flats carry numerous small islands or cays, which in topography and sediment composition are strikingly zoned in response to exposure to prevailing winds and waves. In their natural state the cays carry a littoral thicket of *Cordia*, *Bursera* and *Thrinax*, now largely replaced by coconut plantations. Hurricane *Hattie* crossed the northern part of Turneffe Islands and Lighthouse Reef and the northern barrier reef, accompanied by winds gusting to more than 200 m.p.h. and by a storm surge 45 miles wide and up to 15 ft. above normal high water.

Damage to the reef itself was considerable but superficial: over a narrow zone of the barrier reef more than 90 per cent of the reef corals disappeared, destroying the groove-spur system on the reef front; damage decreased to north and south of this zone, but was greater to the north where winds were mainly easterly. Damage to islands was also concentrated near the storm track. In a central zone many small reef islands disappeared, and most others were overtopped by the storm surge and underwent surface sand-stripping and marginal shoreline erosion. Most of the pre-hurricane vegetation was destroyed in this zone, which extended farther to the north of the storm track than to the south. Outside the high surge area, topographic change was limited to marginal beach erosion with some deposition inland, and the exposure of semi-lithified cay sediments: this zone extended for some 40 miles north and south of the storm track. Outside this area, wind effects were dominant, resulting in the aligned felling of coconuts and other trees, and the defoliation of mangroves, particularly on Turneffe Islands and in the barrier reef lagoon. In the area near the storm track, many nearshore plants disappeared with the erosion of their substrate; and dominants such as *Tournefortia*, *Suriana* and *Borrichia* were no longer to be seen in a 40-mile wide zone north and south of the storm track immediately after the hurricane.

In the southern part of the barrier reef lagoon, particularly on densely vegetated cays off Placencia, and also on larger cays near the storm track which had not been cleared for coconuts, fresh shingle and coral rubble were piled against the vegetation hedge on the windward sides of the islands, above high-water level, and in these cases the main hurricane effects were aggradational rather than erosional. This suggested that the recent clearance of littoral thicket for coconut plantation, especially since 1850, may have had a major influence on the nature of hurricane effects, and may account for the increasing

numbers of cays totally destroyed during such major storms<sup>11</sup>.

#### Geomorphic Changes since 1962

During the 1965 re-survey, islands were revisited, mapped, and photographed from land and air over the whole area damaged by the 1961 hurricane. By contrast with the post-storm changes at Jaluit Atoll, geomorphic adjustments in British Honduras have been minor. Reef recovery, in particular, has been surprisingly small. In the area suffering greatest reef damage in 1961, the only corals still living in any quantity are those which survived the storm itself, particularly *Montastrea annularis*, and in places *Siderastrea siderea*, *Diploria*, and massive *Acropora palmata*. Recolonization has been limited to a few scattered *A. palmata*, all less than 30 cm tall, *Millepora* sp., *Agaricia agaricites*, and infrequent non-frame-building corals such as *Manicina*, *Bumelia*, *Myosiphylia* and *Porites* (*P. astreoides*, *P. furcata*, *P. porites*). Formerly extensive corals, such as *Acropora cervicornis*, are still rare or absent in the most severely damaged areas, and wide areas of flat-lying rubble and dead coral heads are thickly blanketed by non-calcareous algae, chiefly *Padina* with some *Halimeda*. Larger algae, such as *Turbinaria turbinata* on beach rock habitats, are much less numerous than before the hurricane. Sponges and gorgonians, while not numerous in damaged areas, have made a more rapid recovery than the corals.

Why reef recovery is delayed is not clear. The substrate of mobile debris is probably unfavourable to coral colonization, and non-calcareous algae are more rapid colonizers. In these circumstances the estimate made by Stephenson<sup>12</sup> at Low Isles, Great Barrier Reef, of 10–20 yr. being required for reef recovery is probably minimal following such major devastation; it seems likely that the reefs studied in 1959–61 had only recently reached a climax state following the major hurricane of 1931.

Some of the dead reef debris has been moved on to reef crests and island shores to form rubble ridges since the 1962 survey, but otherwise there has been little shoal-water topographic change since the hurricane.

Hurricane effects above high-water level on reef islands appear relatively permanent. Of the seven islands which disappeared in 1961, none has reappeared. In the intertidal and nearshore areas minor changes have occurred in beach profiles, with filling or cutting depending on exposure, but these changes are generally within the range of seasonal fluctuation. In the area of most intense reef damage slight erosion of seaward shores has occurred, consequent on increased exposure. Above and away from beaches there has been no topographic change, except at Northern Cay, Lighthouse Reef, where wind action has built small dunes on a hurricane-deposited sand sheet. In cases where large vegetated islands were reduced to shifting sandbars by the storm, as at Goff's and Sergeant's Cays, continuous minor changes of form and location are taking place, typical of those of unvegetated islands. On islands where rubble and shingle bars and ridges were built during the hurricane, as at Scipio and Colson Cays, these remain essentially intact and are now being vegetated; at Jaluit, by contrast, such bars were largely eroded on the seaward sides of islands in the three years following the typhoon<sup>13</sup>. Gravel and sand sheets on islands and channels cut through island surfaces (except where the latter have been filled by man) remain essentially unaltered.

The most interesting geomorphic changes since the hurricane were found where areas of incipient lithification of island sediments were exposed at and above high-tide level by beach erosion and retreat. This lithification was of two main types: cay sandstone and beachrock. At Big Cay Bokel, Deadman Cays, Grand Bogue Point and Harry Jones, Turneffe Islands, platforms of slightly bonded sand and shingle were uncovered, filled with coconut roots which could be traced upwards into the overlying un-bonded sands. Bonding was so slight that the rock could

be easily crumbled in the fingers. The highest of these exposures reached 60 cm above mean sea-level, and the lowest only slightly above high water level (tidal range about 20 cm), and their height correlated directly with the height of the land behind the beach. By 1965, these exposures had been converted, mainly by case-hardening, into a tough limestone of reef fragments in a carbonate sand matrix.

In all the cases of case-hardening noted, the rock was subject to spray-wetting, and where this was not the case, as at Cay Chapel, the cementation remained weak and the rock friable. The sandy examples are similar to the cay sandstones formerly noted at Harry Jones, Turneffe, and Northern Cay, Lighthouse Reef, and the conglomerates to rubble platforms at Half Moon Cay, Lighthouse Reef. In these cases the existence of lithified platforms above present sea-level had suggested the possibility of recent relative sea-level shifts, but the new data indicate that such high-standing platforms can be produced with stable sea-levels, by the lithification of sub-island sediments exposed by storms. This may have implications in the Pacific, where similar, though larger, topographic features have been used as indicators of sea-level changes<sup>19</sup>. Weakly bonded intertidal beachrock exposed on many islands by the storm (for example, Sandbore Cay, South Water Cay) had been strongly though superficially lithified by 1965.

#### Vegetation Changes since 1962

The major reef island changes in the period 1962-65 have been vegetational. In the zone of major damage, vegetation recovery, as at Jaluit, has depended largely on whether the original soil cover was preserved during the storm (mainly in the interiors of large islands), or whether it was either stripped by surface erosion or buried by fresh sand or rubble deposits (on the margins of larger islands, and across the whole surface of smaller islands near the storm centre). In the case of soil preservation, recovery of herbaceous vegetation and grasses has been rapid, and the ground cover of *Wedelia*, *Canavalia*, *Ipomoea* and *Stachytarpheta* may reach 100 per cent. Where soil stripping occurred the vegetation cover is generally less than 25 per cent, and consists of discrete patches of *Sesuvium*, *Sporobolus*, *Ipomoea* and *Euphorbia*. In cases of soil burial, vegetation colonization depends on the calibre and thickness of the hurricane deposits. Thick nearshore sand sheets may be so densely covered with *Ipomoea* and *Canavalia* that the physiographic effects of the hurricane are largely hidden. Deposits of shingle and rubble especially where thin and overlying a deeply eroded cay surface, have a very patchy cover of *Euphorbia* and *Sesuvium*. Where whole islands were reduced to unvegetated sandbores by the storm, and in 1962 carried a pioneer strand flora dominated by *Portulaca oleracea*, the more stable areas are now covered with carpets of *Ipomoea*, *Canavalia*, *Euphorbia* and grasses.

The dominant nearshore shrubs destroyed by the hurricane in the zone of major damage have made a remarkable recovery. The stripped south shore of Half Moon Cay now has a 50 per cent cover of *Tournefortia gnaphalodes* in patches up to 10 metres in diameter and 1.5 m tall. *Tournefortia* is the most widespread of the nearshore colonizers, but elsewhere *Suriana maritima*, *Sophora tomentosa*, *Borrichia arborescens* and *Conocarpus erecta* reach heights of 1-3 m, regenerating from seed rather than stumps.

Tree recovery has been less spectacular. Coconut trees which retained their crowns during the storm are now fruiting, and trees planted in 1962 now have heights of 1-3 m. Fallen trunks and exposed root nets are rapidly rotting away. *Thrinax* has made a good recovery even where blanketed with shingle in nearshore areas. Of the littoral thicket dominants, *Cordia sebestena* has been most resilient, flowering freely in 1965 from the most shattered stumps; *Coccoloba uvifera*, while less widespread, has also

regenerated from stumps in most cases; but *Bursera simaruba* appears to have been killed in all cases of severe damage.

While vegetation on the sand cays is rapidly reverting to normal, that on mangrove islands has suffered permanent damage. *Rhizophora*, *Avicennia*, *Laguncularia* and *Conocarpus* were defoliated during Hurricane Hattie within a zone extending 20-25 miles north and south of the storm track: the 1965 survey showed that most of this defoliation resulted in death. Particularly in the barrier reef lagoon, mangrove islands are grey and dead over a 50-mile wide zone, the boundaries of which are sharply delimited and pass from mainly dead to mainly living mangrove within 5-10 miles. Within the mortality zone there are small patches of living *Rhizophora* in areas sheltered from extreme winds and waves, but otherwise vegetation growth is limited to fresh colonization by *Batis maritima* and *Cyperus* spp. on higher land. Similar mangrove mortality following major storms has been noted elsewhere (in Guam<sup>14</sup> and Florida<sup>15</sup>) but its precise cause is unknown. As a result of this massive mortality, the formerly abundant *Rhizophora* seedlings are now rare in shoal water areas throughout the central area, and it may be many years before the dead mangrove is replaced by new growth.

#### Economic and Other Adjustments

Following Hurricanes Janet (1955) and Hattie (1961) economic investment on the cays has practically ceased. The failure of coconut rehabilitation projects after Janet has led the British Honduras Government to decline to sponsor further projects after Hattie, and private concerns have made no large plantings. Clearing on one large island for tourist development has ceased, and with the decline of a settled population many of the cays are reverting from intermittently cleared coconut plantation to a coconut-dominated thicket. The change in nature and increasing density of vegetation will undoubtedly increase island resistance to catastrophic damage during later hurricanes<sup>11</sup>. Two destroyed lighthouses have been replaced by automatic lights, and the Government has built small jetties at larger cay and coastal settlements. Few of the cays abandoned after the storm, however, have been reoccupied, and in the central area especially, soil-stripping and the lack of vegetation growth mean that permanent reoccupation may be long delayed. Only at St. George's Cay, a holiday centre near Belize, and at Big Cay Bokel, a tourist centre on Turneffe, has any post-hurricane development taken place, but in exposed locations and lacking vegetational protection further destruction seems inevitable during later hurricanes.

Bird life on the cays has returned to normal since 1962. The nesting of *Sula sula sula*, the pink-footed booby, delayed several weeks in 1962, occurred normally in February-March 1965. Large numbers of pelicans (*Pelecanus occidentalis*), ospreys (*Pandion haliaetus*) and man-of-war birds (*Fregata magnificens*) were seen throughout the damaged area in 1965.

#### Conclusions

The conclusions of the 1965 resurvey reinforce those tentatively made immediately after Hurricane Hattie. In areas of major reef damage, recovery will probably take 25-30 years, or more if the colonization of unfavourable substrates is long delayed. On islands the critical nature of pre-hurricane vegetation is emphasized: with dense littoral thicket aggradation may occur during storms, whereas with coconuts erosion is more probable. Whichever occurs, the geomorphic changes during the storm at and above sea-level appear to be permanent, at least until modified by later hurricane action. Vegetation growth on favourable substrates has been rapid, and with the abandonment of settlements on the cays there may be a reversion to littoral thicket vegetation in place of coconut plantations, with decreased susceptibility to future hurri-

cane damage. Where soils were destroyed, vegetation colonization has been slower, and its future development will probably depend on the rate of soil formation, about which little is known on reef islands. Useful comparisons can be made between these data and the results of the Jaluit Atoll re-survey, and continued observation of reef and island recovery on the British Honduras coast is likely to yield more information on the long-term significance of major storms in the building of coral reefs and islands.

The 1965 re-survey was supported financially by Cambridge University Travelling Expenses Fund, the Cambridge Philosophical Society, and the Royal Geographical Society. I thank Miss Evelyn L. Pruitt, head of the Geography Branch, Office of Naval Research, Washington, for transatlantic transportation, and Mrs. Lenore Smith, Mr. and Mrs. N. B. Stalker, Dr. F. R. Fosberg, Dr. M.-H.

## A POSSIBLE QUANTITATIVE MECHANISM FOR CARCINOGENESIS BY ULTRA-VIOLET RADIATION

By WILLIAM C. SASLAW

Princeton University, New Jersey

BY assuming that cells contain two chemical agents, one advancing and one inhibiting growth, it is possible to construct a simple model which quantitatively accounts for the growth-rate of cancers induced by ultra-violet radiation. This article suggests and outlines a mechanism based on departures of these chemical agents from equilibrium in the cell. It may be regarded as an alternative point of view to Blum's theory<sup>1,2</sup>.

The experimental results for volumetric growth of ultra-violet-induced tumours are described by Blum<sup>3</sup> by the relation:

$$\ln \frac{V_i}{V_0} = \frac{SU_i^2}{(i - \alpha)} \quad \text{For } i > \alpha \quad (1)$$

The volume is  $V_i$  at some initial time  $t = t_0$  and  $t_i$  is the time elapsing from  $t = t_0$  to the time when the volume of the tumour is  $V_i$ . This is usually called the development time. The amount of ultra-violet energy per dose is  $U$ ,  $i$  is the interval between doses,  $S$  and  $\alpha$  are constants. This formula will be derived by considering the growth to be directly related to the influence ratio,  $\gamma$ , of two chemical substances,  $A$  and  $I$ , which respectively advance and inhibit cellular growth:

$$\gamma = \frac{A}{(I - I_0)} \quad (2)$$

Evidence has been presented by Szent-Györgyi *et al.*<sup>4,5</sup> showing that certain tissue cells contain two substances which promote and retard the growth of ascites tumours in mice. However, the interpretation of experimental data on tumour growth rates is not straightforward, as pointed out by Blum<sup>3</sup>, since these rates are coupled to the general metabolism of the animal and will change with age, feeding conditions, etc. In the case of these experiments it is not clear but that regression of tumours may be due to non-selective starvation of local tissue in the cancerous region. Only further research can determine the scope of reversible effects and the seriousness of these objections. For the present, however, we shall neglect such objections in the model which follows.

We suppose the total amount of inhibiting agent in the cell to be governed by radiation decomposition, thermal decomposition, chemical decomposition, and regeneration. In the normal cell the last three processes are in a steady state condition and maintain  $I$  constant. When irradiation occurs, the balance is upset by anomalous decomposition. When ultra-violet light is the carcinogenic agent, the rate of tumour growth is increased each time the dosage

is repeated, indicating that a cumulative process is at work. Thus we might expect the total amount of  $I$  present to be inversely proportional to the accumulated ultra-violet radiation, which is itself proportional to the time over which the dosage has been administered. Differentiating this relationship gives a formula for the rate of change of  $I$  in the cell:

$$\frac{dI}{dt} \sim - \frac{(i - \alpha)}{U i^2} \quad \text{for } i > \alpha \quad (3)$$

We propose a natural generalization of this formula. During a reaction, the change in concentration of a chemical species is usually proportional to the amount of that species present. Our interpretation of  $I$  as a compound in the cell then suggests that we write the decay rate of the inhibitor in a cell in the more general form:

$$\frac{dI}{dt} = - \frac{C(i - \alpha)}{U i^2} I \quad \text{for } i > \alpha; C = \text{constant} \quad (4)$$

This is a hypothesis which can be tested in which  $\alpha$  represents a threshold effect. If  $\alpha$  is a function of physiological conditions—such as previous dosage—and therefore of time, it may be possible to provide apparent immunity by using intervals of less than  $\alpha$  between doses, assuming  $\alpha(t)$  to be a monotonic function. It should be borne in mind that  $\alpha$  may be a function of energy per dose as well as of total dosage. We might, for the present, interpret this threshold effect as a regeneration mechanism for 'normal' semicontinuous dosage. If the intervals between doses are so short that the destruction of the inhibitor becomes a 'normal' condition, the (as yet unspecified) mechanism for maintaining a steady state concentration of the inhibitor will be modified to a new equilibrium-level as the cell adjusts. The value of  $\alpha$  found experimentally is about 0.5, although setting  $\alpha = 0$  and thereby assuming no threshold effect still gives a fair description of experimental data. In this case the accumulated energy would just be  $U i / i$ .

Integrating equation (4) between the limits  $I_0$ ,  $I$ , and  $t_0$ ,  $t$ , gives:

$$I = I_0 \exp \left( \frac{C(i - \alpha)}{U i} \right) \quad (5)$$

where:

$$I_0 = I' \exp \left( - \frac{C(i - \alpha)}{U i_0} \right) \quad (6)$$

Evidently  $I'$  is the amount of inhibitor present at time  $t = 0$ . Equations (5) and (6) are not meaningful for this

model if  $t_0 = 0$  since then  $I = 0$  independent of time. Possibly this indicates a discontinuity such as an initial ionization by an ultra-violet photon which triggers the growth of a tumour. For  $t_0$  finite,  $I_0$  is less than  $I'_0$  and as  $t_0 \rightarrow 0$ ,  $I_0 \rightarrow 0$ . We shall next suggest an interpretation of  $I_0$ .

Since the induction of a tumour requires at least several months, we may assume the rate of decrease of the inhibiting agent to be small and during most of the growth period, for  $t/t_0 \gg 1$ :

$$\frac{O(i - \alpha)}{Ut} \ll 1 \quad (7)$$

This is the criterion for a first-order approximation. Expanding the exponential in equation (5) and ignoring second-order terms in  $O(i - \alpha)/Ut$  we find:

$$(I - I_0) = I_0 \frac{O(i - \alpha)}{Ut} \quad (8)$$

This first-order solution to equation (4) for the decrease in  $I$  could have been obtained directly by assuming that the ultra-violet light perturbs the amount of the inhibitor present in the cell in the manner characteristic of an equilibrium system, that is,  $I = I_0 + (\delta I) + (\delta I)^2 + (\delta I)^3 + \dots$ . Later, however, we will want to return to equations (5) and (6).

It appears that  $I_0$ , which is always less than  $I'_0$  (the amount of inhibitor present initially in equilibrium), is the appropriate fiducial point for the measurement of  $I$  for given values of  $O$ ,  $i$ ,  $\alpha$ ,  $U$  and  $t_0$ . Then  $(I - I_0)$  is the effective amount of inhibitor present. Equation (8), which can in principle be tested experimentally, shows that the effective amount,  $I - I_0$ , of the inhibiting agent present after irradiation is begun is inversely proportional to the total dosage of ultra-violet light received, modified by the threshold constant. As the irradiation continues, the amount of  $I$  present in the cells decreases from  $I'_0$  toward  $I_0$ . It is interesting to examine the dependence of  $(I - I_0)$  on the interval between doses and the intensity per dose. If we define a parameter,  $\lambda$ , equal to the ratio between these quantities:

$$\lambda = \frac{(i - \alpha)}{U} \quad (9)$$

and use equation (6), we may write equation (8) as:

$$(I - I_0) = I'_0 \frac{O}{i} \lambda \exp\left(-\lambda \frac{t}{t_0}\right) \quad (10)$$

Consider equation (10) as a function of  $\lambda$ . If we plot  $(I - I_0)$  on the ordinate against  $\lambda$  on the abscissa, the curve will rise to reach a maximum at  $\lambda_0 = t_0/O$ , after which it will fall. On the rising portion of the curve, an increase in the interval between doses, or a decrease in the energy per dose, will result in an increase in  $(I - I_0)$  and therefore an increase in the effective amount of the inhibiting agent. It is not unreasonable to associate this with a quantitative expression of a recuperation effect. For  $\lambda > \lambda_0$ , either an increase in  $(i - \alpha)$  or a decrease in  $U$  decreases the effective amount of inhibitor. Small doses at long intervals may appear as single irreversible events to the cells and a general recuperation mechanism may not become effective in such circumstances. The dependence of  $\lambda_0$  on  $O$  is consistent with this interpretation. For as  $O$  becomes smaller, the rate of decrease of  $I$ , that is,  $-dI/dt \sim O$ , also becomes smaller. Hence, as the destructive power of the dose is reduced,  $\lambda_0$  increases and there is a larger range of parameters over which recuperation is possible. On the other hand, as  $t_0 \rightarrow 0$ ,  $\lambda_0 \rightarrow 0$ , there is no recuperation, and the model breaks down. This may again be due to the irreversibility of the singularity associated with the initial triggering event.

Let us now suppose that the growth rate is directly proportional to the influence ratio,  $\gamma$ , for cell proliferation. This may work as a chemical control which permits 'cancer templates' or possibly virus particles to replicate more rapidly as the growth ratio increases and thus

somehow convey information of the extraordinary conditions induced by the ultra-violet radiation to neighbouring cells. This modification of information transfer is consistent with the growth of transplanted malignant cells. Here it should be possible to introduce a more detailed mechanism for information transfer and feedback control between cells into this chemical equilibrium model when more experimental work becomes available.

According to Szent-Györgyi<sup>1</sup>, the chemical agent tending to advance growth is the more stable of the two compounds. For simplicity, therefore, we imagine it to be unaffected by ultra-violet radiation and thus maintained at a constant value in the tissue cells. Since the rate of cell proliferation is also proportional to the volume of the tumour, we have:

$$\frac{dV}{dt} = \beta \gamma V = \frac{\beta A U t}{O(i - \alpha) I_0} V \quad (11)$$

where  $\beta$  is a constant. Integrating this between  $V_0$  and  $V_1$ , and  $t_0$  and  $t_1$ , the tumour volume is found to be given, to high accuracy, by the experimental relation (1) for  $t_1 \gg t_0$ , where:

$$S = \frac{\beta A}{2 O I_0} \quad (12)$$

This model also qualitatively accounts for the observed break in the relationship between tumour development time and dose<sup>2</sup>, which suggests that there is an upper limit to the rapidity of tumour growth, as expected from general metabolic considerations. As  $t$  becomes very large in equation (5), we see that  $I$  goes to  $I_0$ , which is given by equation (6). However,  $I$  approaches  $I_0$  asymptotically and for large  $t$ ,  $dI/dt$  is very small. Hence  $\gamma$  is approximately constant. From equation (11) it immediately follows that for the maximum growth rate:

$$\frac{1}{V} \frac{dV}{dt} \approx \text{constant} \quad (13)$$

which is also observed<sup>3</sup>.

As a third comparison of this model with experimental results, we consider tumour growth and development time after irradiation ceases. Equation (4) then becomes:

$$\frac{dI}{dt} = -\frac{EI}{t} \quad (14)$$

where  $E$  is a constant equal to the left-hand side of equation (7) with  $t$  replaced by  $t_0$ , the time at which the dosage is stopped. The amount of inhibitor present at this time is  $I_0$ , which is inversely proportional to  $t_0$ . If this time is less than the development time, the tumour has a volume  $V_0$  which is approximately equal to  $V_1$  since the growth curve is exponential with a long time constant. Applying the same procedure used to derive equation (1) then yields:

$$\ln \frac{V}{V_0} = \frac{\beta A t_0}{I_0(E + 1)} \left[ \left( \frac{t}{t_0} \right)^{E+1} - 1 \right] \quad (15)$$

In the case that  $E \ll 1$ , consistent with equation (7), comparison of equation (15) with equation (1) shows that:

$$t_0 \sim \sqrt{t_1 t_0 - t_0^2} \quad (16)$$

which approximately fits the small amount of data available<sup>4,5</sup>.

This equilibrium formulation has the additional advantage of providing a natural basis for investigation of the reversibility of tumour growth in terms of a stable or unstable equilibrium. At present, however, the experimental data do not appear sufficiently accurate to justify a detailed reversibility analysis.

I thank Prof. H. F. Blum for his advice. This work was begun at the Bartol Research Foundation of the Franklin Institute.

## CARCINOGENICITY OF 'ALDERLIN' (PRONETHALOL) IN MICE\*

By DR. R. HOWE

Imperial Chemical Industries, Ltd., Pharmaceuticals Division,  
Alderley Park, Macclesfield, Cheshire

'ALDERLIN' (I)<sup>1</sup> was shown by Black and Stephenson<sup>2</sup> in 1962 to block specifically cardiac and other  $\beta$ -adrenergic receptors in laboratory animals. In 1964, Alcock and Bond<sup>3</sup> described the production in mice of thymic tumours and other sarcomata associated with the administration of 'Alderlin', which had not appeared to be carcinogenic to rats, guinea-pigs or dogs. 'Inderal' (II)<sup>4</sup> (propranolol) has recently been shown<sup>5</sup> to be about ten times more potent than 'Alderlin' as a  $\beta$ -adrenergic receptor blocking agent and non-carcinogenic to mice<sup>6</sup>, rats, guinea-pigs or dogs<sup>7</sup>.

The major metabolites of 'Alderlin' have been identified<sup>8,7</sup> for the mouse and the rat, and their similarity suggests that it is unlikely that they can be concerned in the carcinogenicity of 'Alderlin'. In particular there was no evidence to suggest that the ethyleneimine (III), a member of a class of compounds known to be carcinogenic<sup>8</sup>, was a minor or transient metabolite of 'Alderlin' in the mouse; nor was there evidence of a sulphate or phosphate ester of 'Alderlin' which might be a precursor of the ethyleneimine (III). Nevertheless some biological

\* The terms 'Alderlin' and 'Inderal' are registered trade marks of Imperial Chemical Industries, Ltd.

and chemical observations led us to test the idea that the ethyleneimine (III) derived from 'Alderlin' might be the actual carcinogen.

The  $\beta$ -chloroethylamine (IV) related to 'Alderlin' was originally prepared<sup>9</sup> as a possible means for providing a slow release of 'Alderlin' *in vivo*. It was known<sup>10</sup> that such  $\beta$ -aryl- $\beta$ -chloroethylamines could be hydrolysed *in vitro* to the parent ethanolamine via an ethyleneimine. The  $\beta$ -chloroethylamine (IV) was as active as 'Alderlin' as a  $\beta$ -adrenergic receptor blocking agent. The onset of  $\beta$ -receptor blockade was rapid and the compound did not show any significantly prolonged activity. The observed biological activity is presumed to be due to hydrolysis *in vivo* to 'Alderlin' via the ethyleneimine (III), and hydrolysis must be rapid because of the speed of onset of  $\beta$ -receptor blockade. This explanation is supported by the fact that, whereas the position isomer (V)<sup>11</sup> of 'Alderlin' is virtually inactive as a  $\beta$ -receptor blocking agent, the  $\beta$ -chloroethylamine (VI)<sup>9</sup> related to it is as active as 'Alderlin'. Hydrolysis *in vivo* to 'Alderlin' via the common ethyleneimine (III) could explain the observed biological activity of (VI). Somewhat surprisingly the  $\beta$ -chloroethylamine (VII) related to 'Inderal' was devoid of  $\beta$ -receptor blocking activity, which suggested that it was not hydrolysed to 'Inderal' *in vivo*. It may, however, have been hydrolysed *in vivo* to the position isomer (IX) of 'Inderal', which is not active as a  $\beta$ -receptor blocking agent. An examination of the hydrolysis of the  $\beta$ -chloroethylamines (IV), (VI) and (VII) and the ethyleneimines (III) and (VIII) has confirmed our interpretation of the biological observations.

The hydrochlorides of (IV), and (VI), were separately heated at 100° C with 1 equivalent of 0.04 N sodium hydroxide for 1 h and then the solutions were cooled and rapidly extracted with ether after liberation of the organic base from its salt by the addition of a further equivalent of sodium hydroxide. Pure 'Alderlin' containing no trace of the position isomer (V) (checked by thin-layer chromatography) was obtained<sup>12</sup> in both cases, thus substantiating the hypothesis that the  $\beta$ -chloroethylamines (IV) and (VI) are converted to 'Alderlin' *in vivo* via the common ethyleneimine (III). Similar conditions applied to the hydrochloride of (VII) gave the ethyleneimine (VIII) as an oil (characterized as the picrate), and not 'Inderal' or its position isomer (IX). The initially elusive ethyleneimine (III) related to 'Alderlin' was obtained by treatment of the hydrochloride of (IV) with 5 per cent sodium bicarbonate and isolation of the free base (IV), which on standing dismutated to a readily separable equimolecular mixture of the hydrochloride of (IV) and the ethyleneimine (III) (an oil, characterized as the picrate). Pure 'Alderlin' was obtained when a solution of the ethyleneimine (III) in 1.1 equivalents of 0.1 N sulphuric acid was heated at 100° C for 0.25 h, cooled, and then rapidly extracted with ether after liberation of the organic base from its salt by the addition of 1.1 equivalents of sodium hydroxide. Under similar conditions the ethyleneimine (VIII) was recovered virtually unchanged. This ethyleneimine was, however, hydrolysed to the extent of 10–15 per cent when the heating period was prolonged to 1 h. The product of the hydrolysis was the position isomer (IX) of 'Inderal'. Pure 'Alderlin' hydrochloride was obtained<sup>13</sup> by heating the hydrochloride of (IV) at 100° C for 2 h with water or

N hydrochloric acid and then evaporating the solution to dryness. Under similar conditions the hydrochloride of (VII) was recovered unchanged. Thus the interpretations put forward to explain the results of the  $\beta$ -receptor blockade experiments were substantiated.

The conversion of the  $\beta$ -chloroethylamine (IV) to 'Alderlin' *in vivo* via the ethyleneimine (III) suggested a means of testing the ethyleneimine hypothesis proposed by Rose and Howe<sup>3</sup> to account for the carcinogenicity of 'Alderlin'. Administration to mice of the  $\beta$ -chloroethylamine (IV), which should produce an equivalent amount of the ethyleneimine (III) *in vivo*, ought to lead to the development of significantly more thymic tumours than would be expected from 'Alderlin' if the ethyleneimine (III) were but a minor metabolite. After the latent period the tumours might also be expected to appear on average at an earlier date in the case of (IV). The ethyleneimine (III) itself was not administered to mice because we did not have a more convenient method of presenting it than as the hydrochloride of (IV).

In an experiment performed by colleagues in these laboratories, groups of 25 male and 25 female mice were given either 'Alderlin' hydrochloride or the hydrochloride of (IV) in the diet at each of the dosage levels shown in Tables 1 and 2. The number of days between the beginning of the experiment and the day on which the thymic tumour was first observed was recorded, and the tumours were afterwards confirmed on post-mortem examination. The experiment with 'Alderlin' terminated on day 454 and that with the  $\beta$ -chloroethylamine (IV) on day 265.

Table 1	
% 'Alderlin' in diet	Day on which thymic tumour was observed
0.2%	♂ 223 ♀ 171, 257
0.1%	♂ 115, 320, 450 ♀ 141, 240, 358, 454
0.05%	♂ None ♀ 172, 220, 428
Control	♂ 228 ♀ None

Table 2	
% (IV) in diet	Day on which thymic tumour was observed
0.2% reduced to 0.15% after 2 months	♂ 78, 92, 92, 100, 101, 103, 104, 113, 117, 120, 130, 141, 146, 149, 151, 167, 183, 190, 210, 253 ♀ 100, 156, 187, 231
Control	♂ None ♀ 158, 142, 153, 173

Unfortunately, the  $\beta$ -chloroethylamine (IV) was selectively toxic to female mice. In the first 90 days seventeen of them died, the majority of which showed severe kidney damage. The test is being repeated using groups of 50 male and 50 female mice, and at a dose-level of 0.1 per cent in the diet. It is hoped that this dose will prove less toxic to the females so that we can determine whether or not the apparently low incidence of tumours is entirely due to the early mortality of the females. Nevertheless the striking increase in the incidence of thymic tumours in the males dosed with the  $\beta$ -chloroethylamine (IV) as compared with the incidence in those dosed with 'Alderlin' strongly suggests that the ethyleneimine (III) could be the carcinogenic agent formed from 'Alderlin' in mice.

Rose has shown<sup>12</sup> for a series of aromatic nitrogen mustards that a certain level of chemical reactivity is necessary if a compound is to be an effective tumour growth inhibitor. If in a similar way chemical reactivity is necessary for tumour initiation then our chemical evidence suggests that the ethyleneimine (VIII) related to 'Alderlin' would probably be non-carcinogenic.

The hypothesis that the  $\beta$ -hydroxyethylamine side-chain of 'Alderlin' might be converted to an ethyleneimine *in vivo* suggests further lines of work. It would be interest-

ing to know whether or not the ethyleneimines (X) and (XI) related to adrenaline and noradrenaline are carcinogenic.

These ethyleneimines might arise as abnormal metabolic products if the normal metabolism of adrenaline and noradrenaline is impaired and might be responsible for the incidence of 'spontaneous' tumours in animals and man. In connexion with the carcinogenicity of aromatic amines, the *ortho*-hydroxylation hypothesis proposed by Clayton<sup>14</sup> and Walpole *et al.*<sup>15</sup>, and the *N*-hydroxylation hypothesis proposed by Miller *et al.*<sup>16</sup>, might be examined from a new point of view. For example, in the case of 2-naphthylamine, 1-hydroxy-2-naphthylamine (XII) and *N*-hydroxy-2-naphthylamine (XIV) are known metabolites which are carcinogenic<sup>17</sup>. The former presumably arises from the latter *in vivo* by an arylhydroxylamine rearrangement involving the *ortho*-quinolimine (XIII). Miller and Miller<sup>18</sup> have demonstrated that such a re-arrangement occurs *in vivo* in the case of *N*-hydroxy-2-acetylaminofluorene. Reduction *in vivo* of the *ortho*-quinolimine (XIII) or 1-hydroxy-2-naphthylamine (XII) could give the  $\beta$ -hydroxyethylamine (XV) which might be metabolized further to the ethyleneimine (XVI).

I thank my colleagues, Mr. P. J. Taylor, who is at present examining the kinetics of the formation and solvolysis of the ethyleneimines (III) and (VIII), and Dr. J. W. Black, Dr. R. G. Shanks, Dr. P. Lemon, Mr. P. A. Melvin, Miss S. J. Alcock and Miss M. J. Tucker for the biological results.

## ROLE OF THE CARRIER IN DEVELOPMENT OF DELAYED SENSITIVITY TO THE AZOPHENYL-ARSONATE GROUP

By DR. VALERIE E. JONES\* and DR. SIDNEY LESKOWITZ

Medical Service, Massachusetts General Hospital, and the Department of Bacteriology and Immunology, Harvard Medical School, Boston

**G**UINEA-PIGS immunized with hapten-protein conjugates produce antibody which is hapten-specific, but exhibit a delayed hypersensitivity which is directed largely toward the protein carrier<sup>1</sup>. When, however, arsanilic acid was used as a hapten and polytyrosine as the carrier, a delayed hypersensitivity resulted which was hapten-specific<sup>2</sup>. Since this represented the only clear-cut case of hapten-directed delayed sensitivity, it became of interest to assess the relative importance of the hapten and the carrier in its production.

The present report concerns the function of the carrier and is a study of the immune response produced by injection of guinea-pigs with the arsanilic acid hapten attached to a variety of molecules which may be roughly divided into the following categories: (1) non-antigenic homopolymers of amino-acids; (2) antigenic co-polymers of amino-acids; (3) proteins of varying antigenicity; (4) proteins which are non-antigenic by virtue of derivation from serum of the same species.

Conjugates were prepared by adding the appropriate amounts of diazotized arsanilic acid to ice-cold solutions of carrier maintained at pH 8-9. Coupling was allowed to proceed overnight to ensure complete reaction, and the resulting coloured materials were purified for the most part by dialysis against running water. All proteins were conjugated with 2 mg of arsanilic acid to 10 mg of protein. Synthetic polypeptides were conjugated with slightly smaller amounts to provide one azophenyl-arsonate group (ars) per 3 tyrosine or lysine residues. Guinea-pig serum albumin (GSA) and insulin were conjugated with excess arsanilic acid for use as skin test antigens.

White male guinea-pigs weighing 400 g were immunized by injection in the four foot-pads of 100 µg of conjugate in 0.1 ml. of complete Freund's adjuvant<sup>3</sup>. Two weeks later they were shaved and depilated and tested for hapten-specific delayed hypersensitivity by intradermal injections of 1 µg N of ars-GSA and ars-insulin. Reactivity to the carrier was assessed by simultaneous injections of 20 µg of the immunizing conjugate and carrier alone, except where these gave non-specific toxic reactions. All skin tests were measured after 24 h to determine the extent of induration and erythema. Table 1 lists the results of immunization with conjugates of arsanilic acid and several synthetic polypeptides. The homopolymers of either tyrosine, histidine, or lysine (purchased from the New England Nuclear Corp., Boston) produced almost universal hapten specific delayed hypersensitivity when this was assessed by reactions to ars-GSA. Reactions to ars-insulin were, however, somewhat greater in ars-polytyrosine immunized animals and less frequent in ars-polyhistidine or ars-polylysine immunized animals. This might in some way reflect contributions by adjacent amino-acids to the reactivity of the azophenyl-arsonate group, since insulin is especially rich in tyrosine and poor in lysine. It is of some interest that the polymers of both L- or D-lysine appeared to be equally effective as carriers for the production of hapten-specific delayed sensitivity.

Despite the effectiveness of polylysine as a carrier, the copolymer of glutamic acid and lysine was ineffective in 8 animals tested. Only one animal, in fact, produced any reaction to the immunizing antigen itself. The addition of tyrosine to the polymer resulted in a carrier

that was universally effective in producing hapten-specific delayed sensitivity. Again, there was a suggestion of some contribution by the tyrosine group to the azophenyl-arsonate reactivity in the markedly greater reactions produced with ars-insulin. The copolymer of glutamic acid, alanine and tyrosine was also an effective carrier for production of delayed sensitivity with all animals showing reactivity to ars-insulin. In confirmation of studies by Benacerraf *et al.*<sup>4</sup>, the polymer synthesized from the D-isomers of glutamic acid, alanine and tyrosine was completely ineffective, even in a ten-fold greater immunizing dose.

The very much larger delayed reactions obtained on skin testing with the immunizing antigen in the case of the polymers of glutamic acid, lysine and tyrosine and glutamic acid, alanine and tyrosine suggested that a good measure of carrier specific reactivity was also present. In other instances, carrier specific reactivity could not be assessed because of the tendency of the conjugates to give non-specific reactions.

The results of immunization with conjugates prepared from a variety of proteins is shown in Table 2. Taken as a whole, a wide range of effectiveness is seen, ranging from total inability to produce hapten-specific delayed sensitivity to almost complete effectiveness. When the various protein carriers are considered in terms of their generally known potencies as antigens in a variety of animal species, some suggestion as to the relation between this property and the ability to produce hapten-specific delayed sensitivity emerges. Thus, bovine ribonuclease (RNase), insulin and serum albumin (BSA) were totally ineffective in the production of hapten-specific delayed sensitivity. Only one animal immunized with ars-BSA showed any reactivity with the heterologous skin test conjugates. While hapten-specific reactivity was lacking, large delayed reactions were seen in all cases after tests

Table 1. RESULTS OF IMMUNIZATION WITH CONJUGATES OF ARSANILIC ACID AND SYNTHETIC AMINO-ACID POLYMERS

Immunizing antigen (100 µg)	No. of reactions/No. tested and average diameter of delayed reactions produced with:		Immunizing antigen (20 µg)
	Ars-GSA (1 µg N)	Ars-insulin (1 µg N)

\* Present address: National Institute for Medical Research, Mill Hill, London, N.W.7.

with the immunizing antigen, as well as the carrier protein alone, thereby demonstrating the large measure of carrier specificity following immunization with these conjugates.

On the other hand, gelatine, haemoglobin and pepsin are ordinarily considered to be poor antigens for antibody production<sup>4-6</sup>. In the form of conjugates with arsanilic acid, all were found to produce some modest degree of hapten-specific delayed hypersensitivity as evidenced by skin reactions to ars-GSA and ars-insulin. Since inherent lack of antigenicity of the carrier protein was felt to be of importance in its ability to produce hapten-directed sensitization, an attempt was made to alter drastically this antigenicity in two cases (BSA and RNase) by oxidation of all disulphide bonds<sup>7</sup>. When arsanilic acid conjugates of oxidized BSA and RNase were used for immunization, small but definite hapten-specific delayed sensitivity was produced in many of the animals. Once again a large degree of carrier specificity could be elicited by tests with the immunizing conjugate and the carrier alone.

Advantage was taken of the fact that guinea-pig serum proteins would not be antigenic in the guinea-pig, and conjugates of two such proteins, albumin (GSA) and  $\gamma$ -globulin (GGG), were used as examples of poor or non-antigenic carriers. When immunization with ars-GSA and ars-GGG was carried out, excellent hapten-specific delayed sensitivity was produced in most of the animals receiving the globulin conjugate but only in an occasional animal receiving the albumin conjugate. In all cases, the immunizing antigen produced marked reactions, but the carrier alone produced none.

While the positive results obtained with ars-GGG seem to be striking confirmation of the contention that poorly antigenic carriers are required, the lack of hapten sensitization obtained with ars-GSA appears to be completely opposed to this hypothesis. One possible way to reconcile these apparently opposing data lies in the recognition that antigenicity of the carrier *per se* need not be qualitatively or quantitatively identical in the conjugate. In other words, immunization with a conjugate cannot be considered merely as sensitization to the native carrier plus sensitization to the hapten. It is well known, for example, that the process of conjugation can denature proteins and can either add or delete antigenic determinants<sup>8</sup>. Thus, it might be that the rather heavy conjugation with arsanilic acid in the present instance so denatured GSA that it became a relatively antigenic material, while GGG was not similarly affected.

These results do not yet allow an exact description of the qualities a carrier must possess to direct sensitization to an appropriate hapten but do suggest that good antigenicity in respect to antibody production militates

against the production of hapten-directed reactivity. This was shown by the ineffectiveness of conjugates of RNase, BSA and insulin to sensitize to hapten. When the antigenicity of such proteins is decreased by oxidation, some increase in ability to sensitize is then seen. The results obtained with the relatively poorly antigenic polymers of amino-acids seem in general to fit this pattern. On the other hand, a poorly antigenic carrier such as gelatine was only occasionally effective, although so few aromatic groups are present in this molecule that it could not be ascertained whether sufficient conjugation did in fact occur. Elastoidin, a tyrosine-rich protein from collagen<sup>9</sup>, was much superior to gelatine, which is poor in tyrosine. This enhancement of carrier effectiveness for directing specificity toward the hapten by the addition of tyrosine groups was similar to that observed with the glutamic-lysine and glutamic-lysine-tyrosine carriers (Table 1).

The failure to obtain sensitization with the polymer of the D-isomers of glutamic acid, alanine and tyrosine, while the polymer of D-lysine was effective, suggests caution in the interpretation of these results in terms of inherent digestibility or recognition of natural and unnatural amino-acid polymers<sup>3</sup>.

While the azophenyl-arsenate group is probably not unique in being able alone to sustain a delayed reaction, the commonly used haptens, such as *p*-aminobenzoic acid, sulphanilic acid and *p*-aminophenylacetamide, do not apparently contain the necessary complementarity or binding potential to produce hapten-specific reactions<sup>10</sup>. The work recorded here demonstrates that the production of hapten-specific delayed hypersensitivity requires not only a particular type of hapten able to express completely this reaction, but that in addition sensitization can be accomplished only by conjugation of this hapten to special kinds of carriers.

We thank Dr. Paul Maurer of Seton Hall College of Medicine and Dr. Thomas Gill of Harvard Medical School for the generous provision of the mixed polypeptides.

## CORRELATION BETWEEN CODING-TRIPLETS AND AMINO-ACIDS

By Dr. S. R. PELC

Medical Research Council Biophysics Research Unit, King's College, London

A TABLE containing 62 nucleotide sequences of RNA codons was recently published by Trupin *et al.*<sup>1</sup> and by Nirenberg *et al.*<sup>2</sup>, who also noted that "amino-acids which are structurally or metabolically related (such as synthesized *in vivo* from a common precursor) often have similar RNA codons". It seemed of interest to explore: (a) what correlations exist between a coding triplet and the structure of the amino-acid coded for; (b) whether the properties of an amino-acid coded by a given triplet on one DNA-strand will in some respects be complementary to those of an amino-acid coded by the complementary triplet (as given by Watson-Crick pairing) on the second DNA-strand. The following correlations, shown schematically in Fig. 1, were found.

The columns headed U and C, that is, those containing all amino-acids the codon of which has uridilic acid or cytidilic acid in second place, enclose the hydrophobic amino-acids, the molecule frequently ends in a methyl group (CH<sub>3</sub>). Those with branched methyl groups are in the U column; OH-groups are seen in the C column. The acid and basic amino-acids have A or G as the second base and are found in the third and fourth columns. No amino-acids; the molecule frequently ends in a methyl. The only exception is serine with AGU and AGC, but this placement seems uncertain since the incorporation in the relevant experiment is scarcely above background.

Simple changes in the structure of an amino-acid are accompanied by a change of one base only in the codon.

		← 2 <sup>nd</sup> →

		BRANCHING	CH <sub>3</sub> FREQUENT	OH	ACID NO	BASIC CH <sub>3</sub>	

Fig. 1. Correlation of codons and amino-acids. The first base in a triplet is noted downwards in the column on the left, the second base horizontally on top, the third base in the sequence U (uridine), C (cytosine), A (adenine), G (guanine) for each row in the narrow column on the right. For example, the codon for tyr, in the third column, top row, is either UAU or UAA. Abbreviations: phe, phenylalanine; leu, leucine; ser, serine; tyr, tyrosine; cys, cysteine; tryp, tryptophan; pro, proline; his, histidine; glun, glutamine; arg, arginine; ileu, isoleucine; met, methionine; thr, threonine; aspn, asparagine; lys, lysine; val, valine; ala, alanine; asp, aspartic acid; glu, glutamic acid; gly, glycine. Smaller letters to the right denote from which compound an amino-acid is derived: PB, propionic acid; OA, oxopropionic acid; Im, imino acid; VA, valeric acid; IVA, isovaleric acid; BU, butyric acid; SU, succinic acid; GL, glutamic acid; AC, acetic acid. The arrows indicate stepwise changes (see text). B =  $\text{H}_2\text{N}-\text{CH}-\text{COOH}$ , the group common to all amino-acids except pro.

Table 1. CORRELATION OF A STRUCTURAL DIFFERENCE OF AN AMINO-ACID WITH CHANGE OF CODON

aa <sub>1</sub>	change	aa <sub>2</sub>	Codon changes from	to
gly	CH <sub>2</sub>	ala	GGU	GCU
ala	O	ser	GCU	UCU
ala	CH <sub>2</sub> -C-H	val	GCU	GUU
ala	OOO	asp	GCU	GAU
asp	CH <sub>2</sub>	glu	GAU	GAA
glu	-OH	glun	GAA	CAA
asp	+NH <sub>2</sub>	aspm	GAU	AAU
asp	-OH	leu	GUU	CUU
val	CH <sub>2</sub>	ileu	GUU	AUU
val	OH	tyr	UCU	UAU
ser	benzene	phe	UCU	UUU
ser	-OH	cys	UCU	UGU
ser	+benzene	tryp	UUG	UGG
ser	-OH	his	UAU	CAU
ser	+8H	thr	UCU	ACU
ser	-OH			
ser	+indole			
tyr	-benzene OH			
ser	+imidazole			
ser	CH <sub>2</sub>			

For example, gly changes to ala by conversion of the terminal hydrogen to a methyl group, the codon from GGU to GCU; the difference between ala and ser, replacement of one hydrogen in the terminal CH<sub>2</sub> group by hydroxyl (OH), is accompanied by a change from GCU to UCU. Altogether fifteen such changes of one amino-acid into another by means of addition of one group connected with a corresponding one-step change in the codon are shown in Fig. 1 and Table 1. Conversely, transformations involving a more complicated rearrangement of an amino-acid molecule usually involve more than one step in the change of the codon, for example, val to met. These conversions are not necessarily steps in the actual synthesis of amino-acids or in the evolution of these compounds. They are additions or rearrangements of single components of amino-acids.

The amino-acids derived from propionic acid, namely, ala, ser, phe, tyr, cys, tryp and his, are situated in such a manner that conversions by a single step are possible; similarly glu and glun derived from glutaric acid, asp and aspm derived from succinic acid. Leucine and ileu derived from caproic acid are in adjacent squares, while the conversion of lys to ileu in two stages also involves changing two bases in the codon. No easy conversion of met into thr, both derived from butyric acid, seems possible.

The third base in a triplet seems to influence the coding only by being either a purine or a pyrimidine (previously suggested for the second base by Eek<sup>3</sup>) or it does not do so at all, especially when C is the second base of the triplet.

The correlations noted here might be explained either by the evolution of the coding system or by assuming that a structural relationship exists between codons and amino-acids. On balance the latter explanation seems to be more likely, since during evolution a random distribution of triplets and amino-acids would be expected if the two are not connected structurally; the probability of achieving by chance the well-ordered and logical arrangement reported here would be negligible.

The enzyme which attaches an amino-acid to its appropriate tRNA must recognize both; the tRNA in turn recognizes the codon on the mRNA. If as shown in this article a close structural relationship between codon and amino-acid exists, it has to be assumed that the two sites on the enzyme are also structurally related.

The second question posed in this article, namely, the possible complementarity of amino-acids, can now be considered in more detail. If thr is found in a given position in a protein chain, the appropriate codon on the mRNA might be ACA, formed from TGT on the DNA. The complementary triplet on the second strand of DNA would be ACA, which in turn would form UGU which codes for cys. In this way pairs of amino-acids complementing each other can be derived. Since the strands of DNA are anti-parallel the second triplet might have to be read backwards but this is not certain<sup>4</sup>. It is obvious that amino-acids with U or C as the second base will complement with those with A or G respectively in the same place. The marked differences between the respective amino-acids appearing in these columns will usually lead to pairing of members of different groups. For example, no acid or basic amino-acid can complement with another acid or basic amino-acid, and amino-acids containing a CH<sub>2</sub> group cannot complement with each other. The properties of pairs of complementary amino-acids are at present being explored by means of model-building.

## HISTONES IN DEVELOPMENT, GROWTH AND CANCER

By PROF. JAY S. ROTH

Institute of Cellular Biology, University of Connecticut, Storrs

UNICELLULAR organisms such as bacteria, protozoa and algae, when placed in a favourable environment containing all the required nutrients, grow at a maximum rate characteristic of the species. So long as adequate supplies of nutrients are maintained and waste products removed, as in a chemostat, this maximum growth will continue. In a simple medium containing salts and a carbon source, the unicellular organisms synthesize all the necessary proteins which in turn catalyse reactions producing all the required precursors for RNA, DNA and other macromolecules, as well as other products used as energy sources or for other special purposes.

A cancer cell is, in terms of its growth and multiplication, similar to the unicellular organisms. It continues to grow in the host or in tissue culture at a rate characteristic of the type of tumour, and probably limited largely by eventual failure of the nutrient supply. The unicellular organisms are in a real sense cancerous (consider, for example, a bacterial infection that overwhelms the body's defences) and conversely the cancer cell is behaving like a unicellular organism in a favourable environment.

The unicellular organism appears to lack any mechanism for growth control. The cancer cell lacks a functional mechanism for growth control.

Since it has been suggested that nuclear DNA-associated histones are the biological repressors which regulate gene action in cells from higher animals<sup>1-3</sup>, it is of considerable interest to ask the following questions:

(1) Do unicellular organisms such as bacteria, protozoa and algae contain DNA-associated histones which are used for regulating gene expression?

(2) Is the possible loss of growth control in a cancer cell a general failure of the histone regulating mechanism, or perhaps a limited failure of this mechanism, particularly with respect to metabolic pathways important to cell division?

It is obvious that these questions cannot be answered unequivocally as yet. The ability to ask the right questions, however, is an important part of scientific endeavour, and there are a number of interesting considerations and some data pertinent to these questions which will be discussed here. These considerations, in turn, may lead to some useful experimental approaches to further our understanding of growth.

With respect to the first question, there is a striking paucity of information concerning histones in unicellular organisms. Only a few scattered reports of histone-like materials in various bacteria, protozoa or algae are found. Most, or all, of these investigations have been carried out by histochemical techniques, and in the few occasions reported it is possible to raise serious doubts as to whether the supposed histone: (1) has a typical histone amino-acid pattern; (2) is associated with DNA in a functional way. In one investigation in which DNA nucleoprotein was isolated from *E. coli* and the amino-acid composition of the protein determined<sup>8</sup>, it proved to be completely different from the typical amino-acid pattern of histones and, in fact, had high proportions of dicarboxylic acids and low proportions of basic amino-acids—just the reverse of histone composition. This, of course, does not refute the possibility that the more acidic protein of the deoxyribonucleoprotein of *E. coli* may function in the same way as histones do in cells of higher animals. Recently Beck and Walker, using a fluorescent immunochemical technique, were unable to demonstrate histones in a number of different trypanosome nuclei<sup>9</sup>. Also, Butler and Godson found no evidence for histone-like protein in nuclear material from *Bacillus megaterium*<sup>10</sup>. In the absence of any good positive evidence for histones in unicellular organisms, the hypothesis that they lack this type of cellular control material is, for the moment, intact.

It is of interest to observe that the Jacob and Monod formulation of the operon system as applied to bacteria<sup>11</sup> does not specifically require histones for its functioning; although it appears quite possible that specific proteins may act as repressors in some cases.

At this point, it may be well to consider that a basic difference between the unicellular organism and the cell of a higher animal is that the latter can undergo differentiation, so that from a single cell type a diverse variety of cells with greatly different functions and properties may be formed. This would certainly require a mechanism for allowing expression of certain gene functions and not others, and for this reason the histone-regulator hypothesis is attractive. Since the unicellular organism does not differentiate in the ordinary sense, it has no need for such a mechanism. (It is true that certain bacteria undergo sporulation which might be considered to be a primitive type of differentiation. This is a process induced, generally, by unfavourable, rather than favourable, growth conditions.) In minimal medium, its entire complement of enzyme systems is presumably functioning at maximum capacity. In enriched medium, it uses (probably in common with cells of higher animals) a system of feedback controls to 'turn off' the synthesis of unneeded proteins.

Thus, addition of a single amino-acid to a minimal medium will prevent the production of all the enzymes involved in the synthesis of that amino-acid. The process is envisaged by Jacob and Monod as a combination of amino-acid with a regulator substance (which may be a protein), which in turn combines with the operon, a regulator gene, inactivating it. So long as the operon is inactive, no gene in the related group produces messenger RNA, and hence no enzyme involved in the synthesis of the particular amino-acid is produced. This is a simple on-off mechanism and if, as suggested, the regulator substance is protein, it need not be a histone. There have been suggestions and there is some evidence that the regulator substance in unicellular organisms may perhaps be RNA<sup>12</sup>, or a more simple molecule, such as an amino-acid or nucleotide, which might act directly at the gene-level on the operon. It has been postulated recently that small peptides may function in this capacity<sup>13</sup>. In unicellular organisms there is no need for an orderly, progressive sequence of gene expression or repression which is required during the development and differentiation of higher animal cells. There is no need for the unicellular organism to stop proliferating at a specific time as is the case for almost all higher animal cells.

It is of special interest to note that many types of tumour cells show a striking lack of differentiation. If histones control differentiation, this is especially significant to the thesis proposed here.

The cancer cell may be visualized, then, as a cell in which the histone control of orderly protein synthesis is faulty. Certain proteins, particularly those involved in or needed for cell division, may be synthesized at a continuing rate, which may be slow or rapid depending on the rate of cell proliferation. Other proteins which would normally be synthesized by the mature cell are not produced at all.

Since we are not certain whether histones control the production of messenger RNA or the sequence of its production, or if they do, how this is accomplished, one can only speculate on how this control may be lost in the tumour cell. Allfrey *et al.* have suggested that acetylation and/or methylation of histones may be the method by which they are activated or inhibited in the performance of their regulatory functions. They reported that acetylated histones lost their ability to repress the activity of RNA polymerase<sup>4</sup>. It is possible to visualize a defective acetylating system, which normally might be highly selective in its action. No striking differences in the overall composition or amount of histones from tumours or homologous or related normal tissues have been detected<sup>14,15</sup> (with one exception mentioned in ref. 7). Although some metabolic differences have been noted<sup>16</sup>, it is possible that differences in the degree of acetylation of different histone fractions from normal and tumour tissues may exist, but thus far this has not been examined. Briefly, the mechanism of the formation of a tumour cell might involve the following steps:

(1) Interference by some chemical, physical or biological agent with the enzyme system or systems responsible for acetylation or other chemical modification of histones resulting in an interference with their proper functioning.

(2) This process might then lead to a fairly random pattern of release of some histone repressions and subsequent synthesis of some enzymes. It might also entail addition of suppressing histones to some genes normally active, the net result being a reversion of the cell to a less differentiated type. There is an example in which the synthesis of the embryonic type enzyme in a tumour, as distinct from the different adult type, occurs and this observation offers support for this concept<sup>17</sup>.

(3) In a few cases the pattern of random changes resulting might be such as to favour continued growth and cell division. It would be expected that all degrees of growth efficiency would result, leading to formation of some tumours capable of proliferating rapidly and others only slowly.

One interesting consequence of this hypothesis is that no gene mutations are required except possibly one—in the gene or gene system related to histone control. Thus a failure to find genetically altered proteins in tumour cells would in general be supporting evidence for a carcinogen mechanism involving histone control. Thus far no clear-cut case has been presented for the production of a protein from tumour cells which has an altered amino-acid sequence, although in some tumours it has been reported that certain enzymes have somewhat altered properties, for example, the *Km* of hepatoma aspartate aminotransferase has been reported to be different from that of the normal liver enzyme<sup>18</sup>. This could well be due to other changes in the cell and not related to a change in the amino-acid pattern of the protein.

(4) If changes in the properties and control activity of histones occur, they would be, presumably, permanent and it would appear to be a difficult, if not impossible, task to selectively reverse them. On the other hand, these changes lead to fairly well defined alterations in metabolic patterns in the tumour, which can be explored for possible rate-limiting reactions or alternative pathways not present or important in normal tissues. Thus, the present-day

research approach which embodies obtaining a further understanding of tumour metabolism as an effective method of devising tumour chemotherapy would not be seriously affected.

Since tumour-causing viruses apparently bring about very selective changes in the cell which then lead to the cancerous state, an examination of viral mechanism of action at the histone- and enzyme-level would seem to be one of the most promising approaches to explore. Particularly important would be the determination of the relationships, if any, between the virus and cell histones, or the acetylation or other chemical modification of cell histones which might alter histone action.

Undoubtedly many other possibly fruitful experimental approaches will be suggested to the investigator and this, it is hoped, will justify the speculation presented here.

## A NEW RED-CELL AUTOANTIBODY IN NZB MICE

By DR. E. J. HOLBOROW

Medical Research Council, Rheumatism Research Unit, Taplow, Maidenhead, Berkshire  
AND

DR. R. D. S. BARNES and MAUREEN TUFFREY

Haematology Research Unit, Hospital for Sick Children, Great Ormond Street, London

MICE of the 'New Zealand Black' (NZB) strain develop autoimmune haemolytic anaemia with red-cell autoantibodies<sup>1</sup>; direct antiglobulin tests are positive in some mice from the age of 16 weeks, and in nearly all mice by 36 weeks<sup>2</sup>. It has been reported that male NZB mice give positive direct antiglobulin tests on average some weeks earlier than females, and that males develop a more severe anaemia<sup>3</sup>. At about the time when red-cell autoantibodies appear, germinal centres and plasma cell proliferation may be seen in the thymus. These thymic changes are found in a majority of the mice and, according to Burnet, may in females precede the appearance of the red-cell autoantibodies, while in males the reverse may be the case<sup>3,4</sup>. Blood from NZB mice has sometimes yielded positive lupus erythematosus cell tests, and Norins and Holmes have reported serum antinuclear factors in about 40 per cent of adult mice<sup>4</sup>.

During investigation of the occurrence of autoantibodies in this and other mouse strains, we have noted in the NZB the appearance of another red-cell autoantibody distinct from that already described.

A colony of about 300 NZB mice has been bred at Taplow from stock obtained from the Laboratory Animals Centre, Carshalton. These originated from Bialohowsky strain stock and were imported from New Zealand at F63. Strict inbreeding has been maintained throughout, and intra-strain skin grafting in the Taplow colony is uniformly successful.

Rabbit antiserum prepared against whole-mouse serum, and absorbed with washed mouse cells, was used for direct antiglobulin tests as described by Holmes, Gorrie and Burnet<sup>5</sup>. Goat antiserum against mouse globulin was conjugated with fluorescein isothiocyanate and absorbed with powdered rabbit liver. This conjugate was used as previously described<sup>6</sup> to carry out indirect immunofluorescent tests for antibodies in mouse sera, which were usually diluted 1:2 in buffered saline before use.

**The new autoantibody.** As a rule, cryostat sections of unfixed calf thyroid tissue were used as a source of nuclear antigens in the immunofluorescent test for antinuclear factor. On one occasion when sections of human thyroid from

a Group O infant were used as well, however, it was noticed that serum from a 36-week-old male NZB mouse gave fluorescent staining of capillaries in the human thyroid tissue, as shown in Fig. 1a. Red cells present in the larger blood vessels were also positively stained (Figs. 1b and 2). Similar staining of vascular contents in human tissue sections was afterwards obtained with sera from many of the older NZB mice. It appeared that the fluorescence seen in the capillaries and other blood vessels was due to staining of the red cells disintegrated by freezing and thawing in the preparation of cryostat sections, rather than to staining of a vascular endothelial component. Similar staining of capillary and vascular contents was obtained with sections of human stomach. Brief immersion of the air-dried cryostat sections in 95 per cent ethanol destroyed their ability to give this staining with positive sera.

Absorption of the anti-mouse-globulin conjugate with mouse  $\gamma$ -globulin (obtained by DEAE column fractionation of mouse serum<sup>7</sup>) inhibited staining by positive sera, although not inhibiting the ability of the conjugate to stain the glomerular component in mouse kidney sections which is related to mouse  $\beta$ -globulin<sup>8</sup>.

Sera giving positive staining of human tissue sections gave similar staining of intravascular red cells in cryostat sections of tissues (kidney, lung, liver, salivary gland, stomach) from NZB mice, as well as from mice of other strains. Furthermore, positive sera showed auto-immune reactivity, staining red cells present in sections of tissues of the mice from which they were taken. In cryostat sections of mouse fetuses taken near term, positive sera stained not only red cells present in the vascular spaces but also nucleated cells morphologically resembling normoblasts. Sera from 111 mice of 12 other strains taken at 6-9 months of age gave no staining of the type described.

**Staining of blood smears.** As well as staining red cells present in cryostat sections of human and mouse tissues, positive sera gave bright staining by indirect immunofluorescence of the red cells in unfixed smears of human or mouse blood prepared and treated as described by Johnson and Holborow<sup>9</sup> (Fig. 3a). Such sera also stained

Fig. 1. Unfixed cryostat section of human infant thyroid (group O) treated with serum from a 9-month-old NZB male, and then with anti-mouse globulin conjugate. Ultra-violet microscopy ( $\times c. 206$ ). *a*, Immunofluorescent staining of capillary contents, *b*, immunofluorescent staining of contents of larger blood vessel.

mouse red cells in smears taken from the donors of the sera, that is, gave an auto-immune reaction. It was noticeable that in positively stained smears of NZB blood, the erythrocytes stained brightly but the many reticulocytes often present stained only faintly or not at all. NZB sera negative against human tissue gave no staining of human red-cell smears, and no staining, or very weak staining, of mouse red-cell smears. This latter mouse specific serum antibody may be that detectable in some NZB sera by indirect antiglobulin test<sup>14</sup>.

Complement-fixing activity was tested for by an immunofluorescent method, in which uptake of added guinea-pig complement in the reaction of red-cell smears with antibody was demonstrated with a rabbit anti-guinea-pig complement antiserum and a goat anti-rabbit serum conjugate. In this way, sera reactive with human erythrocytes in sections or smears as judged by the immunofluorescent antiglobulin test were shown to fix complement with mouse red cell smears.

**Absorption of mouse sera with red cells.** Staining of both human and mouse tissues and human and mouse blood smears could be prevented, partially or completely, by absorbing positive sera with packed washed human group O red cells or mouse red cells. Repeated absorptions at 37° C were necessary; three such absorptions with equal volumes of packed mouse cells removed staining activity of positive sera against both human and mouse tissue and red cells; three absorptions with packed human cells removed most of the staining activity against human

material, and reduced, but did not completely prevent, staining of mouse cells.

However, when the cells used for absorption (even of an excess of serum) were washed and tested with anti-mouse globulin serum, no agglutination was seen. Similarly, smears made from mouse or human red cells used to absorb positive sera showed no immunofluorescence after treatment with anti-mouse globulin conjugate. These findings were consistent with the observation noted below that in some NZB mice the new antibody was detected in the absence of a positive direct antiglobulin test.

**Absorption with red cell stromata.** The foregoing results suggest that the new antibody reacts with antigen present

Fig. 2. Control section of thyroid treated with serum from a 3-month-old NZB mouse. No immunofluorescence of capillaries, or blood vessel contents (top centre) ( $\times 240$ ).

Fig. 3. *a*, Smear of NZB mouse blood treated with NZB serum positive against human red cells; indirect immunofluorescence; *b*, as in (*a*), but treated with positive serum absorbed with human red cell stromata ( $\times c. 185$ ).

in both mouse and human red cells, but not readily available or poorly represented on the surface of the intact erythrocyte; this antigen is evidently rendered accessible in cryostat sections or in blood smears by the effects of freezing and/or drying on red-cell integrity.

Human or mouse red-cell stromata were therefore prepared by the method of Milgrom and Layrisse<sup>11</sup> and used to absorb positive sera, in the proportion of 1 mg of dried stromata powder to 0.1 ml. serum. One such absorption (37° C for 0.5 h) with mouse stromata removed activity against human as well as mouse tissues and smears; a similar absorption with human stromata (Fig. 3b) removed all activity against human tissue or human blood smears, although not invariably all activity against mouse. When the stromata (either human or mouse) used for absorption were eluted with saline at 56° C the eluate obtained stained both human thyroid sections and mouse red-cell smears by the indirect anti-globulin immunofluorescent test.

Absorption with human red-cell stromata also removed the ability of positive sera to fix complement with mouse red-cell smears, as judged by the indirect immunofluorescent method used. By this method, however, eluates from human stromata could not be shown to possess complement-binding activity with red cells present in human thyroid sections.

Results of absorption tests are summarized in Table 1. Age incidence of antibodies. The age incidence of positive direct antiglobulin tests and of the anti-human

Fig. 5. Age frequency as in Fig. 4 in (a) male NZB mice (left), (b) female NZB mice (right). In Figs. 4 and 5 numbers of mice tested at each age are shown.

cross-reacting antibody are shown in Fig. 4. The age-frequency curve of the latter roughly follows that of the direct antiglobulin tests, but with a time-lag of 10 of more weeks. Thus, as might be expected, in individual mice the autoantibody cross-reactive with human red cells was usually found in the presence of a positive antiglobulin test. However, among 120 NZB mice in which development of positive direct antiglobulin tests had been observed, we encountered 5 in which this test afterwards became negative again. Three of these 5 later acquired the new antibody although their anti-globulin tests remained negative during the course of the study. In 4 other NZB mice the direct antiglobulin test never became positive, but nevertheless the appearance of the new antibody was observed.

Figs. 5a and b show the age incidence of the antibodies by sexes. It will be seen that in males the new antibody has a higher incidence than in females. Tests so far performed indicate an incidence of more than 50 per cent in males over 24 weeks, and of about 20 per cent in females over this age. Numbers of mice older than 10–12 months of age so far tested are small, however. The rate at which mice in this series acquire positive direct antiglobulin reactions is somewhat irregular, and does not show the clear difference between the sexes reported by Holmes and Burnet<sup>3</sup>.

Antinuclear factor (ANF). Fig. 4 shows also the incidence of ANF (Fig. 5) in NZB mice. There is little relation between the antinuclear and the anti-red cell antibodies with regard to age incidence; up to 48 weeks of age the incidence of antinuclear factors does not exceed 20 per cent, and is approximately equal in the two sexes. These

Table 1. EFFECTS OF ABSORPTION (a) WITH INTACT RED CELLS OR (b) WITH RED-CELL STROMATA ON IMMUNOFLOUORESCENT REACTIVITY OF POSITIVE NZB SERUM

results do not suggest that development of antinuclear autoantibodies is closely related to the progress of disease in these mice. It may be mentioned here that in a strain of O57 brown mice we have found a higher incidence of ANF (about 50 per cent) without gross evidence of accompanying disease. Antinuclear antibodies have been reported in mouse strains A/J, O57 BL/6 (ref. 12), A/He and O57 BL/6J (ref. 13), and we are investigating their incidence in some other strains.

### Discussion

These results show that as well as the mouse-specific autoantibodies against red cells already known, NZB mice may also develop a different autoantibody, reactive with antigens present in both human and mouse red cells. It appears that the antigenic sites with which this second antibody reacts are not abundantly present on the surface of intact erythrocytes, but are readily accessible in dried red cell smears or in red cell stromata. Tests for cross-reactivity of this antibody with the red cells of other species are being undertaken. That this antibody indeed differs from that responsible for the positive antiglobulin tests of NZB mouse red cells is further attested: (a) by its occasional occurrence in mice with negative antiglobulin tests; (b) by its complement-fixing activity, which has proved to be demonstrable not only by immunofluorescence, but also by conventional complement-fixation tests. The spontaneous appearance of this second autoantibody in a considerable proportion of NZB mice more than 24 weeks old suggests that its production may be related to the thymic changes which have already begun to take place by this age, and this relationship needs closer study. One possibility to be considered in this connexion is viral infection, for it is known that this can give rise to anti-red cell antibodies<sup>14</sup>, and that the effects of thymic deficiency may be averted in mice by germ-free rearing<sup>15</sup>. The effect of rearing NZB mice in a germ-free environment is at present being examined. The question also arises whether the higher incidence of the new anti-

body in males than in females is causally related to the greater severity of the anaemia<sup>7</sup> in males, as already noted<sup>8</sup>. Like Holmes *et al.*<sup>8</sup>, we have succeeded in transferring the direct antiglobulin reaction to young NZB mice by injecting intraperitoneally washed spleen cells from older mice already antiglobulin positive. We have, in addition, shown that when the spleen cells are obtained from donors positive for the new antibody described here, the ability to produce this new antibody is also transferred, so that after a few days the sera of the young recipient mice begin to give positive immunofluorescent tests with human thyroid sections.

In experiments now in progress we are investigating whether the haematological effects of transferring spleen cells from older NZB mice to young mice of this strain differ according to whether the cell donors are positive or negative for the new antibody. The effects of immunization with human red cell stromata on young NZB mice are also under investigation. We thank Miss N. Bell and Miss J. Holliday for assistance.

## SOIL HUMIC ACID AS A HYDROXYPOLYSTYRENE: A BIOCHEMICAL HYPOTHESIS

By DR. BERNARD J. FINKLE

Western Regional Research Laboratory, Western Utilization Research and Development Division, Agricultural Research Service, U.S. Department of Agriculture, Albany, California

THE stable humic acid of soil has an unknown chemical structure; it is considered to be a complex phenolic polymer formed from unknown biological precursors<sup>1</sup>. This article presents the hypothesis that hydroxystyrenes formed under natural conditions may play an important part in forming soil humic acid. This concept followed on the finding that hydroxystyrenes are produced during bacterial decarboxylation of certain phenolic acids of plant origin (4-hydroxycinnamic acids)<sup>2</sup> and the realization that soil humic acid in many of its described properties resembles oxidized polystyrenes.

The hypothesis is suggested on the basis of the following information: 4-hydroxycinnamic acids and their derivatives are abundant in fallen, decaying vegetation; conversion of the acids to hydroxystyrenes involves simply a known enzymatic decarboxylation; styrenes and hydroxystyrenes thus formed would spontaneously polymerize and oxidize under natural conditions<sup>3</sup>; and oxidative polymerization of such hydroxystyrenes would give rise to polymers which, it appears, could account for many of the properties characteristic of humic acid.

The enzyme responsible for decarboxylation of 4-hydroxycinnamic acids, forming hydroxystyrenes, was found in widely occurring, free-living species of *Aerobacter*<sup>4</sup>. It readily and specifically attacks the hydroxy-

cinnamic acids (structure 1), *p*-coumaric, caffeic and ferulic acids, common plant constituents.

The product hydroxystyrenes, after decarboxylation, have the general structure:

Hydroxystyrenes could also arise through bacterial degradation of other plant products, such as hydroxycoumarins and perhaps flavonoids, which can yield their chemically related hydroxycinnamic acids. Lignin also is closely related to the hydroxycinnamic acids; lignin from conifers is often considered a polymer of coniferyl alcohol:

During plant decay, lignin is reported to undergo depolymerization and demethoxylation and, further, is oxidized to aromatic carboxylic acids<sup>4,5</sup>. Decomposition of lignin to hydroxycinnamic acids<sup>6</sup> and the participation of lignin in forming mature soil humic acid<sup>6</sup> have been documented.

The proposed hypothesis is that humic acid forms through the following reactions in soil: liberation and/or synthesis of hydroxycinnamic acids from the decay of plant litter (the presence of *p*-coumaric acid and related phenolic acids in soils has been reported<sup>7</sup>); decarboxylation of the hydroxycinnamic acids by common micro-organisms, producing hydroxystyrenes; and oxidation, polymerization, and copolymerization of the resultant hydroxystyrenes to humic acid.

Two main questions would have to be answered to verify that the proposed processes contribute in significant amount to the formation of soil humic acid. (1) To what extent do decarboxylation of hydroxycinnamic acids and polymerization of their hydroxystyrene products take place in soil? There are no data bearing on this. (2) To what extent would the properties of such hydroxypolystyrenes, oxidized to an unknown degree, resemble those of humic acid? This question can be examined. As a first approach toward evaluating the hydroxypolystyrene hypothesis, I will enumerate several properties of humic acid preparations that are similar to and consistent with the expected properties of the complex polystyrenes described.

Soil humic acid has been repeatedly reported as a (1) stable<sup>8</sup> amorphous aromatic polymer of varying degrees of molecular condensation<sup>1</sup>. It is (2) water and alcohol insoluble<sup>1</sup>, to a degree depending, as with other polymers, on molecular weight<sup>9</sup>. Humic acid, a major component of the soil humus complex, gives to soils a (3) friable character (comparable in this respect to the 'soil conditioner' effect of synthetic vinyl polymer additives<sup>10</sup>).

Humic acid is (4) soluble in alkali<sup>11</sup>. Such solubility would be consistent with the properties of either a hydroxypolystyrene (which would form phenolate salts in alkali solutions) or a carboxylic acid, or a mixture of these.

Humic acid contains a (5) great concentration of stable free radicals. These have been interpreted as arising from oxidized phenolic compounds, such as quinones and quinhydrone<sup>12</sup>. Hydroxystyrenes oxidized at the quinone-level would, likewise, display free radical behaviour.

The (6) molecular composition of soil humic acid is similar to that of an oxidized polystyrene. Composition data on humic acid preparations fall within a recognized range, but with some variation dependent on the soil of origin. Gillam<sup>13</sup>, analysing nitrogen-free preparations of humic acid, found the average C—H—O proportions 61—4—35 per cent. A hydroxypolystyrene quinone of the structure:

(derived from oxidative decarboxylation of, for example, *p*-coumaric acid) has the C—H—O proportions 64—4—32 per cent. The undecarboxylated parent (*p*-coumaric acid) oxidized similarly would have the proportions 56—3.1—41 per cent. Analyses of humic acid indicate about 0.5 mole carboxyl group per mole of aromatic monomer when a formula weight of 200 is assumed<sup>1</sup>. A 50—50 copolymerized mixture of styrene and carboxylic acid at the foregoing oxidation-level would have the C—H—O proportions 60—3.6—37 per cent. Methylation in some degree (see structure 1) would bring the figures still closer to the ratios found by Gillam. A small proportion of methylated 3-hydroxy groups and other variations of structure, such as hydroxylated side-chains and oxidative ring cleavage products, are evidenced by humic acid

analyses<sup>14</sup>. Some of the variability in composition among soil humic acids may be accounted for by these variations. Of course, composition data, particularly when variable, can only be suggestive; such data cannot of themselves prove the presence of any particular chemical structure.

Of particular interest, however, is the observation that during ageing of soils changes occur in chemical composition: more mature, highly aromatic, highly condensed soils have more C relative to O+H and more O relative to H<sup>1</sup>. These changes are consistent with continuing oxidation and decarboxylation of copolymerized hydroxycinnamic acids to oxidized hydroxystyrenes in a polystyrene copolymer. The (7) ease of decarboxylation of unknown structural components of humic substances has been repeatedly confirmed and attributed to constituent carboxylic acids<sup>15</sup>. The analytical figures of Schwartz and Asfeld<sup>14</sup> on heat decarboxylation of extracts of lignite soil agree well with this picture.

The presence of carboxylic acids in a humic acid copolymer would also account for its (8) base exchange properties. The molecules could be interconnected and copolymerized by cross-linkages between the side-chains, as in polystyrene, thus leaving the carboxyl groups free.

Another type of copolymerization, or perhaps entrapment within a polystyrene matrix, could take place with aromatic amino-acids derived from protein degradation of organisms in the soil. The (9) nitrogen content of humic acid preparations varies widely (< 0.5 to > 6 per cent) among soils<sup>1,11,15</sup>. The variation, and the ease with which nitrogen content is often reduced by simple extractions, has led many to conclude that the nitrogen compounds in humic acid are not derived from primary humic acid precursors, are hence variable in composition and dependent on the chance proximity of nitrogenous biological products<sup>1,15</sup>.

It appears, then, that many of the important characteristics of soil humic acid may be reconciled in terms of a complex, variable polymer with oxidized hydroxypolystyrene as a major structural feature. The decarboxylation-polymerization reactions that have been described almost certainly take place in vegetable compost to some extent. Both plant hydroxycinnamic acids and ubiquitous *Aerobacter* species (and possibly other species) which decarboxylate them are bound to occur in juxtaposition in many (or most) soils<sup>16</sup>. Continuing decarboxylation, polymerization and oxidation could proceed for a long period of time. Subsidiary reactions of demethoxylation and hydroxylation, reaction with nitrogen-containing residues from amino-acids, etc., would be assumed to also occur in the soil at various rates, some slowly, in a complex manner, over many years. At what rate the described decarboxylations and polymerizations actually do proceed in soil; whether the rates of hydroxystyrene monomer formation and its polymerization, copolymerization, and oxidation could, or do, account significantly for the formation of humic acid in soils: these are questions which require investigation.

## MITOSIS IN HYBRID CELLS DERIVED FROM MOUSE AND MAN

By PROF. HENRY HARRIS and DR. J. F. WATKINS

Sir William Dunn School of Pathology, University of Oxford  
AND

G. LE M. CAMPBELL, DR. E. P. EVANS and DR. C. E. FORD, F.R.S.

Medical Research Council, Radiobiological Research Unit, Harwell

IN a previous article some characteristics of heterokaryons produced by fusing together HeLa and Ehrlich ascites cells were described<sup>1</sup>. In cultures containing such composite cells it was observed that some of the cells rounded up in mitosis were very much larger than those normally seen in cultures of HeLa or Ehrlich ascites cells. Preliminary cytological investigation of these large mitotic cells revealed that many of them contained a mixture of metacentric and acrocentric chromosomes. Since published reports indicated that there may be one or at the most two metacentric chromosomes in tetraploid Ehrlich ascites cells<sup>2</sup> and relatively few acrocentric chromosomes in HeLa cells<sup>3</sup>, it seemed likely that metaphase figures containing large numbers of both were derived from hybrid cells which originally contained both human and murine nuclei. This observation has now been confirmed by a more detailed examination: hybrids produced by the fusion of HeLa and Ehrlich ascites cells are indeed capable of undergoing mitosis, and, at metaphase, they contain chromosomes characteristic of both mouse and man.

The HeLa cells were obtained from a stock suspension culture and the Ehrlich ascites cells from the peritoneal cavity of Swiss mice. A suspension containing  $2 \times 10^7$  cells of each type was treated with 8,000 haemagglutinating units of ultra-violet-irradiated Sendai virus, as previously described<sup>1</sup>. The treated cell suspension was then seeded into four 20-oz. medical flat bottles, each containing approximately 40 ml. of culture medium. The cultures were maintained at 37° C and samples were taken at 24, 48 and 72 h for cytological investigation.

'Colcemid' (CIBA), at a final concentration of approximately  $10^{-5}$  M, was added to the culture, and 1.5 h later the bottle was shaken to free the cells in mitosis from the glass. The freed cells were sedimented by centrifugation for 3 min at 200g, resuspended in warm hypotonic sodium citrate solution (1 per cent wt./vol.) and left to stand at room temperature for 10 min. The cells were again sedimented and then fixed by several changes of a mixture of 3 parts ethyl alcohol and 1 part glacial acetic acid. Preparations were made by air drying<sup>4</sup>, either from the fixative or from 45 per cent acetic acid. Similar preparations were obtained from Ehrlich ascites cells taken directly from carrier mice.

The chromosome count in 37 out of a sample of 40 Ehrlich ascites cells fell within the range 73–80 with a weak mode (9 cells) at 76. The counts in the remaining three cells were 62 (possibly a broken cell), 151 and 154. Thirty-four of the cells examined contained a long metacentric marker chromosome like that described by previous workers. Many cells also contained up to three additional marker chromosomes. Two of these were very similar, perhaps identical, long acrocentric chromosomes with prominent sub-terminal (distal) secondary constrictions. The third was a long acrocentric chromosome with a closely proximal secondary constriction (Fig. 1). Otherwise, the chromosomes were typical of the mouse, that is, they were all acrocentric with minute (or undetected) short arms. The range in length between the longest and shortest (about 4:1) was, however, clearly greater than in the normal somatic chromosomes of the mouse (about 2.5:1).

Most of the mitotic cells in the mixed culture were immediately recognizable as HeLa cells by their chromosomes. Counts made in 53 of them revealed a sharp mode at 57 (36 cells), an 'inner' range of 54–59 and an extreme range of 48–82. The mode is much lower than any reported by previous workers<sup>5</sup>. The chromosome set as a whole was clearly human in character. Only three decisive marker chromosomes were identified, although detailed examination would almost certainly reveal more in the D, E, F and G groups. One of these marker chromosomes had an arm ratio of approximately 4:1, as in the B group, but was as long as, or even longer than, the presumptive No. 1 and No. 2 chromosomes. The other two markers correspond to the C group in length, but have arm ratios of 5:1 or 6:1, one being somewhat longer than the other and having a relatively longer short arm. A cell with the modal number is illustrated in Fig. 2 and the markers are indicated. This cell contains 13 acrocentric

Fig. 1. Ehrlich ascites cell ('tetraploid' line) at metaphase. 77 chromosomes. Arrows indicate the three marker chromosomes described in the text.

Fig. 2. HeLa cell at metaphase. 57 chromosomes. Arrows indicate the three marker chromosomes described in the text.

chromosomes, of which nine and two, respectively, are not obviously distinct from the normal *D* and *G* groups and two are intermediate in length between them. These are the only chromosomes of the HeLa karyotype that could be confused with any of the Ehrlich ascites chromosomes (other than the metacentric marker already mentioned).

Mitotic cells were present at all three times of gathering, but the best preparations were obtained from the 72-h material and these alone were used for detailed examination. Hybrid cells in mitosis (Figs. 3 and 4) were easily identified in these preparations by their large number of chromosomes and the high proportion of acrocentrics among them. An unselected sample of 28 cells was examined, and counts ranging from 111 to approximately 412 chromosomes were recorded. Twenty-three of the counts are believed to be substantially correct and are set out in Table 1 in comparison with the expected counts from various combinations of Ehrlich ascites and HeLa nuclei, minimum, modal and maximum values being calculated from the modes and 'inner' ranges already given. On this basis eight of the cells fall in the 1 Ehrlich/1 HeLa class, five in the 1 Ehrlich/2 HeLa class, two in the 1 Ehrlich/3 HeLa class and two in the 2 Ehrlich/2 HeLa class. The remaining six cells could be the products of fusion between cells with numbers of chromosomes lying outside the 'inner' range or, more probably, artefactual counts due to breakage of the rather fragile cells and loss of chromosomes during cytological processing. Of the five cells excluded from Table 1, one had 112

Table 1. COUNTS OF THE CHROMOSOMES IN 28 HELa/EHRlich ASCITES HYBRID CELLS

Nuclear combination	Expected count			Actual counts
	Min.	Mode	Max.	
1E+1H	125	133	139	111, 116, 118, 120, 122, 129, 131, 132, 133, 134, 137, 153, 171, 172
1E+2H	177	190	198	173, 181, 185, 189, 193
2E+1H	198	211	219	
1E+3H	239	247	257	230, 241
2E+2H	250	266	278	271, 275 -
3E+1H	271	287	299	

chromosomes but was quite clearly broken, three were estimated to contain 150, 300 and 300 chromosomes, respectively, and one was the cell with 412 chromosomes already mentioned (Fig. 4). Two of the 28 cells exhibited large numbers of structural changes in the chromosomes, particularly 'double minutes', but other changes, at both the chromatid and chromosome levels, were also identified (Fig. 4).

A detailed analysis was made of one of the cells (Fig. 3). Of a total of 181 chromosomes, 72 (including one marker) were identified as of Ehrlich ascites origin, 100 (including two markers) as from HeLa, and nine could not be assigned to either. These are very close to the numbers expected from the fusion of one modal Ehrlich cell and two modal HeLa cells.

These hybrid mitotic figures could have arisen in four ways: (1) by chance association of HeLa and Ehrlich cells which have dried out together to give a single group of chromosomes; (2) by coalescence of HeLa and Ehrlich cells simultaneously in mitosis; (3) by mitosis in synkaryons (heterokaryons in which the individual nuclei have fused together to form a single nucleus); (4) by synchronous mitosis in the nuclei of multinucleate cells. The first possibility can be ruled out on the grounds of the evenness of distribution of the chromosomes in many spreads, the thorough mixing of HeLa and Ehrlich chromosomes in most spreads and the rarity of free Ehrlich ascites cells in mitosis. This line of Ehrlich ascites cells does not grow *in vitro*, and only one example of an Ehrlich ascites cell in mitosis was found in the mixed culture. This last consideration also eliminates the second possibility, which would in any event require the very improbable juxtaposition of several single cells simultaneously in mitosis to account for mitotic figures containing several chromosomal sets.

We now have evidence that hybrid mitotic figures can be produced by both the third and the fourth mechanisms. Mitotic prophase has been seen in synkaryons of various sizes, and there is thus no doubt that at least some of these cells can undergo mitosis. The evenness of distribution and thorough mixing of the chromosomes in most of the spreads made from the 72-h culture strongly suggest that most of the hybrid mitotic figures seen at this time arose in this way. In earlier experiments mitosis was not seen in the nuclei of multinucleate cells, but in the present experiments prophase has been seen in such nuclei in preparations made 24 h and 48 h after cell fusion. In most cases only some of the nuclei in the multinucleate cells were in prophase, while others remained in interphase, a situation apparently similar to that described by Stubblefield<sup>8</sup> in multinucleate cells induced by 'Colcemid'. In view of the fact that only a small percentage of HeLa-Ehrlich heterokaryons show synchrony of DNA synthesis in their nuclei<sup>1</sup>, the occurrence of asynchronous nuclear mitoses is not surprising. A small number of multinucleate cells have, however, been seen in which the individual nuclei enter prophase together. Hybrid mitotic figures may therefore also be produced by synchronous metaphase in multinucleate cells. Fig. 5 illustrates the two mechanisms by which hybrid mitotic figures may be produced. Two synkaryons are shown in prophase, and, in the same field, a dikaryon with both nuclei in synchronous prophase. If post-mitotic reconstitution in these multinucleate cells gives rise to cells with a single large nucleus or cells with fewer nuclei than

Fig. 3. Hybrid cell at metaphase. 181 chromosomes. Arrows indicate 2 HeLa and 1 Ehrlich ascites marker chromosomes.

Fig. 4. Hybrid cell at metaphase. Approximately 412 chromosomes (centromeres). Note large number of structural changes.

Fig. 5. Two synkaryons in prophase and a dikaryon with both nuclei in synchronous prophase

were present originally, the progressive nuclear fusion which is characteristic of these hybrid cultures might be produced by this mechanism rather than by direct coalescence of interphase nuclei, as previously suggested<sup>1</sup>.

While it is thus clear that hybrid cells produced by fusing together HeLa and Ehrlich ascites cells are capable of undergoing mitosis, the question remains whether these cells can multiply continuously to give rise to a strain of mixed parentage. Populations of heterokaryons made with high doses of virus and consequently containing relatively large numbers of nuclei per cell show no net growth: the number of hybrid cells remains more or less stationary for about 5 days and then gradually falls<sup>1</sup>. It is therefore clear that most of these multinucleate cells do not give rise to viable progeny. This observation is borne out by the fact that giant mitotic figures containing several chromosomal sets, like that shown in Fig. 4, disappear from the cultures within 5 or 6 days. In cultures examined 10 days after cell fusion the only hybrid mitoses

seen were those in which the number of chromosomes approximated to 2 chromosomal sets. Table 1 shows that even at 72 h hybrids containing only one chromosomal set from each parent cell were already the commonest type of hybrid undergoing mitosis. This type of hybrid thus resembles the spontaneous hybrids discovered by Baraki *et al.*<sup>2</sup> in mixed cultures of cell lines from the same species: in both cases the hybrid cells appear to contain one set of chromosomes from each parent cell. It is not unlikely that the hybrids discovered by Baraki *et al.* also arise through the action of viruses, especially in the light of recent experiments which indicate that para-influenza viruses may be carried by cell lines in a latent form<sup>3</sup>.

Further examination of the reproductive capacity of HeLa-Ehrlich hybrids is frustrated by the fact that these hybrids are invariably overgrown in the cultures of HeLa cells. Several attempts have been made to find cultural conditions which would select for the hybrids, but so far without success. It is, however, of interest to note that a rapidly growing strain of rat-mouse hybrid cell has recently been isolated by the use of selective media<sup>4</sup>. The fact that the parent cells are derived from different animal species is not, therefore, in itself a barrier to continued reproduction of the hybrid progeny. In the present case it may be the inability of the Ehrlich ascites cell to maintain itself *in vitro* which is responsible for the poor growth of the HeLa-Ehrlich hybrid relative to the HeLa cell. The technique of cell fusion permits the exploration of a wide range of other combinations<sup>5</sup>.

## NUCLEIC ACID SYNTHESIS AND THE MITOTIC CYCLE IN MAMMALIAN CELLS TREATED WITH NITROGEN MUSTARD IN CULTURE

By DR. A. G. LEVIS, DR. G. A. DANIELI and DR. E. PICCINNI

Institute of Zoology, Comparative Anatomy and Genetics, University of Padua, Italy

A DIFFERENTIAL inhibition of DNA and RNA synthesis by nitrogen mustard (methyl-bis[ $\beta$ -chloroethyl]amine, or HN2) has been observed in various types of animal cells<sup>1,2</sup>. In guinea-pig kidney cells adapted to *in vitro* growth (strain ROP), a dose of 2  $\mu$ g/ml. of HN2, which reduces survival to negligible values (0.002 per cent), inhibits cell division severely, but allows the cells to grow in size for many days: the RNA content of such undividing giant cells may attain a seven-fold increase, whereas their DNA content scarcely doubles<sup>3</sup>. Data are also available which seem to indicate that RNA synthesis still remains DNA-dependent after HN2 treatment<sup>4,5</sup>.

The increased amount of DNA per cell, which was also observed after treatment with HN2 by other authors<sup>3,4,6</sup>, has been interpreted to mean that the cells synthesise DNA up to the pre-mitotic level, and then DNA synthesis ceases. Gelfant<sup>7</sup> suggested that the inhibitory effect of nitrogen mustard is felt in the G2 phase of the cell cycle: HN2 would thus inhibit cell division after DNA synthesis has occurred, but it would not prevent the synthesis of DNA in those cells which

have not as yet reached the G2 period. The hypothesis has also been advanced that the blockage of cells in a pre-mitotic phase of the cycle could be due to some change induced in a protein of the nucleus, perhaps of the chromosomes, which must occur in the G2 period in order for cells to enter mitosis<sup>8</sup>.

On the other hand, the cross-linking action of difunctional alkylating agents (such as HN2) on nucleic acids<sup>9</sup> suggested to us a mechanism based on a direct action of the agent on the DNA molecule, which could also explain the relative insensitivity of RNA synthesis, as compared with DNA synthesis<sup>10</sup>. It may be envisaged that the degree of cross-linking between the complementary deoxy-ribose chains produced by the particular HN2 concentration used may still allow a partial unfolding and separation of the twin polynucleotide chains, but not the complete partition of the newly formed double strands in two daughter chromatids. Therefore, alkylated chains may still serve as templates for a single round of DNA synthesis, but no division could follow, and subsequent DNA synthetic cycles would thus be impeded. A scheme of this sort would therefore explain why DNA synthesis

Fig. 1. *A*, Fraction of labelled *AUP* cells in untreated (broken line) and in HN2-treated (unbroken line) cultures, incubated for 1 h with 1.7  $\mu$ Ci/ml. of tritiated thymidine (specific activity: 1.9 c./mM) at different times after treatment. At each point 500 cells were scored. Data from two separate experiments. *B*, Fraction of labelled *AUP* cells in cultures treated with HN2, incubated up to 24 h with 0.5  $\mu$ Ci/ml. of tritiated thymidine. Some of the cultures were incubated during the first, some during the second, some during the third day after treatment. At each point 500 cells were scored. Data from two separate experiments.

stops only after the cell has doubled its normal DNA content. On the contrary, DNA-dependent RNA synthesis, which does not seem to require transition of primer DNA to the single-stranded form<sup>11</sup>, would not be affected by any degree of cross-linking of DNA molecules.

If this were so, cells would be stopped in a phase the nearer the end of the *S* period, the more related are the two processes: DNA duplication and partition of the new molecules into daughter chromatids. Moreover, the effects of DNA alkylation on the progress of cells along the cycle would differ according to the position of cells at the time of treatment. We have therefore undertaken an investigation of the action of nitrogen mustard (2  $\mu$ g/ml.) on human amnion cells grown *in vitro* (strain *AUP*), the results of which are described in detail elsewhere<sup>12</sup>. The first point we observed, in agreement with the findings of other authors<sup>13</sup>, is that cells which were in *G2* at the time of treatment are not prevented by HN2 from entering mitosis, and are able to complete cell division. In fact, all mitotic phases drop to zero values only after a time which corresponds to the length of *G2* (about 3 h) in the particular strain used. About 20 h after treatment, mitosis is resumed, but we observed only prophase and abnormal metaphases (showing chromosome fragmentation); not one anaphase or telophase was observed until the end of the fourth day (more than 4,000 cells were scored per point). Moreover, after continuous incubation with tritiated thymidine, labelled mitoses (abnormal metaphases) appear in cultures treated with HN2 only after the 20th h, whereas, by treating the cells after 3 h of tritiated thymidine incubation, the frequency of labelled metaphases rises as in control cultures. On the other hand, the percentage of labelled cells, after continuous incubation with the radioactive precursor, rises in HN2 as in untreated cultures.

These results seem to confirm the hypothesis that *G2* cells are not blocked by HN2 during the first mitotic cycle, but are prevented from entering mitosis during the second, and show at the same time that all the cells are able to pass at least once throughout *S*, and are blocked afterwards. If, as suggested, the inhibitory effect of the mustard is felt in *G2*, the block would there-

fore be placed just at the beginning of this phase. In these experiments, however, the DNA content per cell can reach much more than the double per cell level, even if a differential inhibition of DNA and RNA synthesis is still induced by HN2 (Table 1). Moreover, the percentage of labelled cells after a 'pulse' of tritiated thymidine given at different times after treatment with HN2 may reach 90–100 per cent values between the 16th and the 24th h, and still at the end of the second day the percentage of cells in *S* is almost double that of controls (Fig. 1*A*).

The cells must therefore be blocked in *S*, where they are able to synthesize DNA for several cycles of replication, up to levels 4–5 times greater than normal. Cells which eventually escape the block are definitively stopped in metaphase, where the alkylation of DNA results in chromosome fragmentation. That these cells cannot complete a new cycle is confirmed by the fact that no cell enters from *G1* into *S* after the first day of treatment (Fig. 1*B*).

These results are not in disagreement with those previously reported, which seemed to indicate a blockage of DNA synthesis at the pre-mitotic level<sup>2,3</sup>. In fact, the cells treated with HN2 had up to twice the mean normal amount of DNA found in an asynchronous control population; as the last included cells which had already doubled DNA (those in *G2* and in the first phases of mitosis) the double cellular level found in treated cultures really exceeded the normal pre-mitotic level. Only Caspersen *et al.*<sup>4</sup>, by using quantitative cytochemical methods on single mouse fibroblasts grown *in vitro*, have shown that DNA synthesis was arrested in all the cells when they had attained the pre-mitotic content, within a 48-h period after treatment with HN2. But it cannot be excluded that the synthesis would have continued later on: the same conclusion in fact could have been reached from our data also (Table 1), if we had limited the observations to the second day after treatment. It must be noted that strain *AUP* cells are much less sensitive to HN2 than *ROP* cells we have previously used<sup>12</sup>; survival at the same dose of 2  $\mu$ g/ml., measured by colony counts, is increased in the former by a factor of 60. HeLa cells, which show

Table 1. THE AVERAGE CONTENT OF DNA AND RNA PER CELL (STRAIN AUP), AFTER TREATMENT WITH HN2 (2 µg/ml)\*

Days after treatment:	0†	1	2	3	4	5
DNA A	1.0	1.3	1.6	1.8	2.6	3.8
B	1.0	1.4	1.8	2.6	3.6	5.2
RNA A	1.0	1.5	2.2	3.4	3.8	5.6
B	1.0	1.8	2.8	4.0	7.0	10.1

\* From cultures of known cellular density, nucleic acids were extracted with perchloric acid and determined spectrophotometrically, following a method described elsewhere<sup>12</sup>; three cultures per point were used. Data from two separate experiments (A, B) are reported.

† The unit at zero time refers to the average of three determinations made on exponentially growing cultures, just before treatment.

an intermediate degree of sensitivity to HN2, are able to synthesize DNA for 5 days, up to a level three times greater than the mean control value<sup>14</sup>. The different action on DNA synthesis could therefore be related to a different inactivation of the enzymes or other features of the biosynthetic pathway, which seem also to be involved in the process of inhibition of DNA synthesis<sup>15</sup>. Recently the different sensitivity of cells to alkylating agents has been shown to depend on the activity of enzymes which repair damaged DNA<sup>16</sup>.

In summary, whatever their position in the cycle at the time of treatment, all the cells are able to proceed and are stopped only when they reach S. The blockage of cells in this phase could still be due, as suggested before, to the induction of cross-linkages between the complementary deoxyriboside chains, the partition of which would be impeded. Clearly the two events, DNA duplication and partition of the new molecules into daughter chromatids, must be much closely related, as suggested also by the model for chromatid duplication and organization proposed by Taylor<sup>17</sup>.

Perhaps the most significant of our results, independently of the molecular mechanism which it determines, is the possibility for cells to undergo several cycles of DNA replication without cell division (and therefore without partition of the synthesized DNA). As a matter of fact, there is considerable evidence that each segment of the chromosomal DNA replicates only once during each cell cycle. Taylor's detailed model seems to explain this known feature and to provide the necessary control

mechanism for the single DNA reproduction in the cell cycle. However, as Taylor has suggested<sup>18</sup>, the control mechanism could be prevented by breakage of DNA between the normal sites for replication. The fixation of the deoxyriboside chains, which is known to follow if some of the cross-links induced by difunctional alkylating agents split off<sup>9</sup>, could therefore open new primer sites on the DNA molecule and permit several cycles of replication during the same cell cycle. This mechanism could also explain why DNA which is alkylated *in vitro* by HN2 serves as a better primer than the non-alkylated DNA<sup>19</sup>. The possibility that a fraction of the DNA molecule may replicate more than once before the completion of normal duplication of the rest of the molecule has recently been shown for the chromosome of *E. coli*<sup>12</sup>. It seems that the experimental conditions which cause such a defective replication result also, in this case, in the induction of new primer sites on the DNA molecule.

## SHERPA PHYSIOLOGY

By DR. S. LAHIRI

Department of Physiology, Presidency College, Calcutta

AND

DR. J. S. MILLEDGE

Department of Thoracic Surgery, Christian Medical College and Hospital, Vellore, Southern India

THE physiological investigation of the Himalayan high-altitude residents (Sherpa) which was sponsored by the Indian Council of Medical Research and carried out on the Himalayan School House Expedition, 1964, led by Sir Edmund Hillary (sponsored by *World Book Encyclopedia*, Chicago), recently concluded its programme after a period of three months in the field. The physiology team was organized and led by Dr. S. Lahiri of the Department of Physiology, Presidency College, Calcutta. Two other members of the team were Dr. J. S. Milledge, Christian Medical College, Vellore, Southern India, and Mr. A. K. Bhattacharyya, Presidency College, Calcutta. Mr. Bhattacharyya was, however, unable to continue his participation in the altitude programme.

The expedition set out from Katmandu in the middle of September 1964, and reached the base camp, Lukla, 9,500 ft. (2,900 m), after 14 days' trekking. The physiology camp was established on October 5, 1964, at 16,000 ft. (4,880 m) within a day's walking distance from Lukla.

Three lowlanders and four Sherpa residents occupied the camp and served as subjects of the physiological programme. There were visitors, both lowlanders and Sherpas, from time to time, who also served as subjects for some of our experiments. The camp was taken down and the members returned to the base camp on December 6, 1964, and flew out to Kathmandu from there by December 11.

We had a weekly cycle of weather change, 3-4 days' fine weather with clear skies followed by mist, snowfall and short storms. Afternoon mist was almost a regular feature. The barometric pressure in early October was 425 mm mercury which gradually decreased to 418 in December as winter set in. The maximum daily variation was 3 mm mercury, a fall being recorded in the evening.

A large dome tent was used as the main laboratory. Morning laboratory tent temperature immediately after sun-rise was below freezing, often down to minus 10° C. During the working hours the inside temperature fluctu-

ated between 7° and 24° C. Exercise experiments were carried out mostly on a bicycle ergometer outside the tent under a shade and a few climbing experiments on a mountain slope.

The main objective of this investigation was to investigate the physiology of the Sherpa high-altitude residents, and compare the results with those of the lowlanders acclimatized to the same altitude. This was the first systematic attempt to examine the Sherpa physiology which not only recorded new data on an isolated group of people but also advanced knowledge about some aspects of human adaptation to altitude. The following principal physiological investigations were carried out:

(1) *Respiratory regulation.* The ventilatory response to carbon dioxide and hypoxia were examined at rest with respect to alveolar carbon dioxide pressure and oxygen pressure using a technique worked out by Lloyd and Cunningham and their associates in the Laboratory of Physiology, University of Oxford.

(2) *Muscular work.* Oxygen consumption, pulmonary ventilation, alveolar gas tension and arterial blood pH were measured under resting condition and during muscular work at 475, 900 and 1,285 kg/min on the bicycle ergometer. In some experiments the effects of breathing oxygen at higher and lower pressures were also recorded. The relationship between ventilatory function and work was also investigated in a few climbing experiments.

(3) *Heart rate.* Heart rates were systematically recorded in all the experiments mentioned in section (2).

(4) *Maximum oxygen consumption and recovery.* Oxygen consumption, ventilation and heart-rates were measured during and after work at highest work rates the subjects could manage for about 3 min. The recovery was followed up to 15 min on stopping work. Blood was taken for lactate estimation at 3rd, 10th and 15th min on stopping work.

(5) *Acid base balance.* Arterial blood and cerebro-spinal fluid pH, arterial oxygen content and capacity, and carbon dioxide content of arterial blood and cerebro-spinal fluid were measured at rest. Tonometry of the cerebro-spinal fluid and oxygenated and reduced blood at different carbon dioxide pressures were performed at 38° C and pH carbon dioxide pressure and contents were determined.

(6) *Arterial oxygen saturation.* This parameter which gives a measure of diffusion limitation was measured at rest and exercise breathing air and oxygen.

(7) *Urinary steroids and Na/K ratio.* The urinary 17-ketosteroids and ketogenic steroids and Na/K ratio were measured in the lowlanders and the residents before and after the administration of adrenocorticotrophin gel at altitude to determine the response of the adrenal cortex. These experiments were also performed in the lowlanders at sea-level.

(8) *Electrocardiogram.* Complete electrocardiograms of lowlanders and Sherpas were taken at 9,500 ft. (2,900 m) and 16,000 ft. (4,880 m). Sea-level records of the lowlanders were also made.

(9) Blood-haemoglobin values of the Sherpa residents were determined to compare their values with those of the published data of the Andean residents of similar altitude. Haemoglobin of the lowlanders was also determined.

(10) *Alveolar and mixed venous gas pressures.* Alveolar oxygen pressure and carbon dioxide pressure and mixed venous carbon dioxide were determined in the lowlanders and residents at different altitudes. In these experiments, a few lowlanders examined had residence at altitude for a period up to four years.

## Results

*Respiratory regulation.* The high-altitude residents breathe less than the recently acclimatized lowlanders both at rest and in different grades of exercise, but breathe more than the average sea-level values. The ventilation carbon

dioxide response line was lower (shifted to the left) at altitude but there was no marked difference between the two groups. The carbon dioxide sensitivity also was not markedly different in the two groups, but the Sherpas showed a markedly reduced sensitivity to hypoxia. For example, the effect on Sherpas of reducing the alveolar oxygen pressure from 200 to 40 mm mercury at constant carbon dioxide pressure was to increase the ventilation by only 10 per cent of that found in lowlanders.

*Alveolar and blood gas tensions.* Alveolar and mixed venous carbon dioxide pressures were higher in the residents. Along with this, arterial blood and cerebro-spinal fluid pH were also lower in the Sherpa residents compared with the lowlanders at altitude, which seems to tie up in a cause and effect relationship. The calculated arterial and cerebro-spinal fluid carbon dioxide pressure was higher in Sherpa residents.

Tonometry experiments showed that there was no significant difference in the buffering power of cerebro-spinal fluid and of blood between the two groups to account for the difference in pulmonary ventilation.

*Blood pH.* Arterial blood pH in the acclimatized European members turned more alkaline in exercise but significantly acidic in the Indian member studied. Acidic change may be related to the lactate accumulation in blood of the latter subject. This pH value, if anything, changed to acidic side in the Sherpa residents. A corresponding change in the alveolar gas pressures was also noted, that is, carbon dioxide pressure remained almost unchanged in the Sherpa subjects but decreased in the European subjects. Thus the Sherpa subjects were able to maintain higher arterial oxygen pressure at a given saturation of oxygen, because of the Bohr effect on the oxygen dissociation curve.

*Oxygen breathing.* Breathing a gas mixture enriched with oxygen to sea-level pressures during exercise greatly diminished pulmonary ventilation in the lowlanders but usually produced no definite effect on the resident's ventilation. Thus in the lowlanders oxygen breathing increased not only alveolar oxygen pressure but also alveolar carbon dioxide pressure and arterial hydrogen-ion concentration, while in Sherpas oxygen breathing resulted in little change in carbon dioxide pressure or pH.

*Arterial oxygen saturation.* Resting arterial blood oxygen saturation was similar in both groups, which was about 80 per cent. Moderately heavy exercise while lowering this saturation increased the alveolar oxygen pressure due to hyperventilation. Thus alveolar-arterial oxygen gradient became large, showing a limitation of oxygen diffusing capacity of the lung at altitude. Oxygen breathing raised the saturation to normal values both at rest and in exercise. The experiment on arterial oxygen in exercise could be performed in a lowlander subject only. But capillary blood drawn from a warm hand for pH measurements on other subjects including Sherpas showed visibly a difference: blood on oxygen inhalation was bright red.

*Heart rate.* Resting heart rates were lower in the Sherpas and the normal maximum heart rate of 190-200 was achieved in two subjects at the work rate of 1,285 kg/min. The maximum heart rate in the lowlanders was lower, between 140-160, at 900 kg/min. However, oxygen breathing at sea-level pressure raised the maximum in the lowlanders. In Sherpa residents oxygen lowered the rate at all levels examined. Breathing low oxygen mixtures at altitude depressed the rate: very severely in the lowlander, less so in the Sherpas. There was no appreciable difference between the two groups in the rate of recovery after stopping work.

*Oxygen debt.* Oxygen consumption at rest and during work on the bicycle ergometer including the maximum was similar in both groups but the oxygen debt appeared to be smaller in the Sherpa subjects. Resting blood lactate was similar but its level after maximum and during recovery period was lower in the Sherpas.

Lactate concentration in the cerebro-spinal fluid was similar in both groups, about 25 mg/100 ml. Although the cation ( $\text{Na}^+$  and  $\text{K}^+$ ) concentration was similar and did not change from the sea-level values,  $\text{K}^+$  concentration both in cerebro-spinal fluid and plasma was in the higher range in the Sherpa subjects.

**Haemoglobin.** In general, haemoglobin concentration in the residents was lower than the lowlanders exposed to the same altitude.

**Electrocardiograph.** All electrocardiographic records were within the normal limits. Normal axis in the lowlanders was vertical or showed often a deviation to the right. A few in Sherpa group showed horizontal axis.

These observations show that the altitude residents respond less to the hypoxic stimulation of altitude than

the well-acclimatized lowlanders. They select a different combination of cardiovascular and respiratory function from the acclimatized lowlanders to achieve the same physiological end. It seems that acclimatization, as the term is usually understood, consists of a number of short-term adjustments of a lowlander, enabling him to survive and perform more efficiently under conditions of low oxygen tension at altitude. But in the high-altitude residents more fundamental long-term changes have come about perhaps at cellular level which result in more efficient working of the organism and a certain reversal of the short-term adjustments when the first crisis is overcome. Whether these fundamental changes are genetic in origin or acquired over many years or generations of high-altitude residence is one of the unsolved problems of altitude physiology.

## BIOLOGICAL PROPERTIES AND RADIOSENSITIVITY OF TUMOURS : DETERMINATION OF THE CELL-CYCLE AND TIME OF SYNTHESIS OF DEOXYRIBONUCLEIC ACID USING TRITIATED THYMIDINE AND AUTORADIOGRAPHY

By DR. ANNA GOLDFEDER

Cancer and Radiobiological Research Laboratory, Department of Hospitals and Department of Biology, New York University, New York

AS part of a series of investigations on biological properties and radiosensitivity of tumours, their proliferating cycle has now been examined in this laboratory. Specifically, I have compared the kinetics of two types of tumours with varying growth rates, both indigenous to the same host. The analysis was based on the quantitative autoradiographic estimation of the number of cells incorporating tritiated thymidine as a precursor in DNA synthesis, thus permitting determination of the time the cell spends in the various phases of its cycle. The data were plotted and the curves are shown in Figs. 1 and 2. Inspection reveals a striking difference between the  $T_s$  phase of the two tumour-types. The  $T_s$  phase of the spindle cell tumour is approximately twice as long as that of the epithelial tumour. (There are also some differences between the other phases of the life-cycle of these tumour types but these will not be considered at present.)

The usefulness of carbon-14- and phosphorus-32-labelled precursors and improved autoradiographic techniques for determining the cell cycle and the time of DNA synthesis in growing plants was first recognized by

Fig. 1. Curves illustrating the percentage of labelled mitoses in the spindle cell tumour, plotted against time between tritiated thymidine injection and killing of the tumour-bearing mouse. Each symbol represents average counts of several tumour nodules of two or three mice

Fig. 2. Curves illustrating the percentage of labelled mitoses in the epithelial cell tumour, plotted against time between tritiated thymidine injection and killing of the tumour-bearing mouse. Each symbol represents average counts of several tumour nodules of two or three mice

Howard and Pelot<sup>1</sup>. This technique was later applied to human bone marrow cells cultivated *in vitro*<sup>2</sup>. Since thymidine is one of the nucleosides of the DNA molecule<sup>3</sup> and is specifically utilized by proliferating cells (mammalian, plant or micro-organisms) for synthesis of DNA, its successful tritiation<sup>4</sup> led to its widespread use in the examination of cellular kinetics and the timing of DNA synthesis. Because it emits  $\beta$ -particles of low energy (0.019 MeV), thereby permitting high resolution of autoradiography, it is a valuable tracer for identification of those cells which are actively engaged in DNA synthesis prior to cell division.

During the past several years, tritiated thymidine and the autoradiographic technique have found wide application not only in kinetic investigations of a variety of normal mammalian cells, but also in investigations of neoplastic cells, particularly those growing in ascites form. (The references pertaining to these investigations are cited in Table 1.) However, I know of only one report in the literature on the use of tritiated thymidine in examinations of the mitotic cycle and DNA synthesis time in a mouse mammary tumour grown in a solid form

Table 1. DNA SYNTHESIS TIMES ( $T_s$ ) OF VARIOUS CELL TYPES

Cell types	Medium	$T_s$ -Phase (h)	Ref. No.
Bone marrow	<i>In vivo</i>	12-15	2

in isologous hosts<sup>5</sup>. I am not aware of any comparative investigations of the kinetics of two morphologically and biologically diverse but genetically isologous tumours, both grown in parent hosts. Thus, we thought that the two types of mouse mammary tumours which have been under investigation in this laboratory for several years would constitute a particularly suitable test system for an examination of the dynamics of cellular proliferation.

These tumours are: a slow-growing epithelial one, designated DBAH, and a rapidly growing spindle cell type, designated DBAG. Both were developed from the mammary gland tissue of the inbred DBA/212 strain of mice and are propagated by serial transplants in isologous hosts. Their history and biological properties have been described<sup>6</sup>. Several of their metabolic and morphological properties examined at cellular and sub-cellular levels, as well as their response to ionizing radiation, are also known<sup>7,8</sup>. Their latent periods are 4-6 days for the spindle cell tumour and 10-12 days for the epithelial tumour. The spindle cell tumour was in its 458th passage and the epithelial tumour in its 38th passage of serial transfer at the time of these examinations.

In my investigations I used the following method: Male mice were implanted with several tiny particles of either epithelial or spindle cell tumour. Each tumour-bearing mouse was injected intraperitoneally with 0.3 c.c. aqueous solution containing 25  $\mu$ c. of tritiated thymidine. (The tritiated thymidine with specific activity of 1.9 c./mmole was obtained from Schwarz Bio-Research, Inc., Orangetown, New York.) Since the mice ranged in weight between 20 and 25 g, each received approximately 1  $\mu$ c./g body-wt. After injection of the labelled precursor, the mice were killed by cervical dislocation at hourly or bi-hourly intervals and the tumour nodules immediately removed. These procedures were carried out during a 30-h period.

Small particles were randomly removed from each tumour with sharp razor blades, fixed for 1 h in 3:1 alcohol-acetic acid and then kept overnight in a 10 per cent neutral formal-saline solution. Autoradiographs were made of deparaffinized sections 2-3  $\mu$  thick and dipped in nuclear photographic emulsion, NTB or NTB<sub>2</sub>, obtained from Eastman Kodak, Rochester, N.Y. After 10-12 days' exposure in a freezer at -20° C, the autoradiographs were developed for 6 min in Kodak D-19 at 16° C and fixed for 10 min in Kodak acid fixer. The usual procedure of washing, staining with Harris haematoxylin and eosin, and dehydrating followed. Labelled mitotic figures were identified by the presence of activated silver grains. The cells were usually heavily labelled and the background was low. In a number of instances mitotic counts were made on Feulgen-stained squash-preparations and compared with those of sections. Generally, fairly good agreement was obtained, indicating that my sections 2-3  $\mu$  thick provided good autoradiographic efficiency. This is in agreement with Kisilevski, Baserga and Vanpotic<sup>9</sup>. The number of labelled and unlabelled mitotic figures in all phases was determined for 100-200 mitoses per mouse.

The percentage of labelled mitotic figures, including all phases, was plotted against time after administration of tritiated thymidine into the tumour-bearing mice. The results are presented in Figs. 1 and 2. Each point constitutes average counts of 3-4 tumour nodules of the same mouse and also averages of two repeated experiments for each time-interval. Confidence intervals of positive mitotic counts among all mitotic counts observed are expressed using the formula:

$$p \pm 2 \frac{\sqrt{p(1-p)}}{n}$$

where  $p$  = percentage of positive mitoses,  $n$  = total counts and resulted in  $p \pm 10$  per cent. (Calculated by Dr. A. Berger, of the Statistics Department of Public Health, New York City.)

The estimation of the time-intervals of the cell-cycle and of DNA synthesis is made according to the method originally used by Quastler and Sherman for mammalian cells<sup>10</sup>, and afterwards by many other investigators. In brief, the phase of the cell-cycle was divided as follows:  $T_{G_1}$  = post-synthetic, pre-mitotic period from the time of injection of the labelled precursor to the earliest time of appearance of labelled mitotic figures. In the case of the spindle cell tumour (Fig. 1),  $T_{G_1}$  phase lasted about 1 h, whereas in the epithelial tumour (Fig. 2),  $T_{G_1}$  was about 2.5 h. The frequency of the labelled mitotic figures rises rapidly after the  $T_{G_1}$  period and reaches a peak of approximately 76 per cent for the spindle cell tumour and about 80 per cent for the epithelial tumour. The time of DNA synthesis ( $T_s$ ) was estimated from the points between the 50 per cent level, that is, where half-labelled mitoses intercept on the ascending and descending portions of the curve. Inspection of the curves shows that the average  $T_s$  for the spindle cell tumour is 12 h and for the epithelial tumour 6 h.

The number of labelled mitoses in the spindle cell tumour decreased (after the peak) to approximately 27 per cent at 16 h after administration of the labelled precursor. At this point a second wave of labelled mitoses started and reached 56 per cent at 20 h. These labelled mitoses could well constitute the daughter cells of the initially labelled mitotic figures which had passed through interphase and had arrived at the next division. Following the 20-h period, a gradual decrease in labelled mitoses occurred in this tumour, reaching 3 per cent labelling 30 h after the administration of the labelled precursor.

Regarding the epithelial tumour, it can be seen in Fig. 2 that a gradual decrease in labelled mitoses occurred after the peak, resulting in 27.6 per cent at 11 h and in a plateau lasting about 4 h. Following this period, a slow rise in labelled mitoses occurred, reaching a second peak of approximately 57.5 per cent at 20 h. Then followed a decline to about 35 per cent at 24 h and about 28 per cent at 30 h after the administration of tritiated thymidine.

The generation time for both tumours was then determined. This is the distance from the beginning of the rising points of the curve at zero to the far portion of the trough (allowed in these cases where  $T_{G_1}$  and mitoses are short compared to  $T_s$  time). For both types of tumours, it was found to be approximately 16 h.

The post-mitotic, pre-synthetic period ( $T_{G_2}$ ) was obtained by subtracting the sum of the  $T_{G_1}$  and  $T_s$  periods from the generation time. According to the results (Figs. 1 and 2),  $T_{G_2}$  lasted 3 h for the spindle cell tumour and 7.5 h for the epithelial tumour.

In the field of cellular kinetics the most reliable data are generally deemed those obtained for  $T_{G_1}$  and  $T_s$  phases. Consequently, these two phases, and particularly the  $T_s$  phase, are emphasized in the work recorded here. A detailed analysis of the literature reveals that  $T_s$  values differ not only between various cell types but also between cells of the same morphological classification. Examples are listed in Table 1. Additional results can be found in a table compiled by Oehlert, Seemayer and Lauff<sup>11</sup>.

There are differences in opinion among investigators as to the constancy of  $T_s$  phase for various cell types. For example, Cameron<sup>13</sup> expressed the opinion that the 6-8 h  $T_s$  period should be regarded as a constant for various cell types. Wolfberg<sup>13</sup> reported a  $T_s$  period of 13.5 h for the stomach epithelium of the mouse. Another report<sup>14</sup> cites a  $T_s$  period of 30 h for mouse ear epithelium. This extremely long  $T_s$  period is assumed to be caused by the 17° C temperature of the mouse ear, which is lower than the 37° C at which the mammalian cells normally metabolize. Baserga<sup>15</sup> reports a  $T_s$  of 17 h for the Ehrlich ascites tumour cells grown in female mice and a  $T_s$  of 11 h for those grown in male mice.

The question arises as to why there exists a wide range in the  $T_s$  period, which is one of the most important phases in the life-cycle of the cell. This question becomes even more significant if one compares the  $T_s$  period of the two types of tumours examined here, both of which are of the same genetic derivation and are propagated in isologous parent hosts. The difference in their  $T_s$  periods could be solely attributed to differences in their inherent cellular composition.

To shed light on this problem, the following explanations are offered:

(1) Some of the metabolic events which are involved in DNA synthesis may be slower in the spindle tumour cells than in the epithelial tumour cells. This assumption is based on results of previous experiments<sup>6,7</sup>, which showed that the oxidative phosphorylation capacity of the spindle cell tumour mitochondria is significantly less efficient than that of the epithelial cell tumour mitochondria. Electron microscope investigations<sup>8</sup> which revealed that the mitochondria of the spindle cell tumour are fewer in number than those of the epithelial tumour and of inferior quality, containing fewer membranes (cristae), attested to these results. Furthermore, there appeared to be fewer and smaller ribonucleoprotein particles (RNP) in the spindle cell tumour than in the epithelial tumour<sup>16</sup>. This would indicate that the epithelial tumour cells, which are richer in the essential cytoplasmic components, are more efficient in the production of the necessary precursors for DNA synthesis. Conversely, the spindle tumour cells produce these precursors less efficiently, thus limiting the rate of DNA synthesis and extending the  $T_s$  period. These results are in line with recent concepts concerning the participation of the cytoplasmic compounds including mitochondria in DNA synthesis<sup>17,18</sup>.

(2) The number of chromosomes may also play a part in the time of synthesis of DNA. It has been found by cytophotometric measurements and by chromosome counts<sup>19</sup> that the spindle tumour cells contain 32 per cent tetraploids, 6 per cent octaploids, 49 per cent diploids and 13 per cent aneuploids, whereas the epithelial tumour cells contain 85.5 per cent diploid, 10 per cent aneuploid and 4.5 per cent hypoploid cells. Thus, in order to replicate two or four times more DNA for tetra- or octa-ploid cells, more time could well be required, particularly in the case of the spindle cell tumour, where the nucleotide pool is inadequate.

Conclusions reached by Defendi and Manson<sup>20</sup> that the number of chromosomes has no bearing on the phase of DNA synthesis do not seem to be borne out by closer scrutiny. These authors tabulated results from the literature on the relationship of chromosome numbers to DNA synthesis ( $T_s$ ), and expressed the opinion that the duration of  $T_s$  is independent of the number of chromosomes. However, their table reveals that in the case of Ehrlich *ELT* tumour containing 92 chromosomes, the  $T_s$  phase ranges from 13-14 h; in the majority of cells containing 42-46 chromosomes, and in two cases of cells with 60 chromosomes, the  $T_s$  period ranges from 6-8 h. It would therefore seem that the question of the influence of chromosome numbers on the  $T_s$  period will have to be further explored.

Based on the previous observations on the structural and functional properties of these two tumour types, the inference is strong that the longer  $T_s$  of the spindle cell tumour, relative to that of the epithelial tumour, is caused by the diminished or impaired synthesis of the necessary nucleotides. The thought is suggested that the clue to the variation in  $T_s$  phases of other cell types may be found in the availability of free nucleotides.

## A PERMEABILITY FACTOR (TOXIN) FOUND IN CHOLERA STOOLS AND CULTURE FILTRATES AND ITS NEUTRALIZATION BY CONVALESCENT CHOLERA SERA

By PROF. JOHN P. CRAIG

State University of New York, Downstate Medical Center, Brooklyn, New York

THIS article reports the finding of a heat-labile factor in sterile filtrates of both cholera stools and young cultures of *Vibrio cholerae* which evokes induration and a prolonged increase in capillary permeability following intra-

cutaneous injection in guinea-pigs and rabbits; and which is neutralized by convalescent sera from cholera patients.

Although Koch in 1884 considered cholera to be essentially a toxicoosis, caused by a poison excreted by the

causative organism, most workers during the ensuing decades have favoured the view that *V. cholerae* does not produce a soluble exotoxin, but rather contains endotoxins which are liberated on autolysis or disruption of the organisms. Many workers, using a wide variety of extraction procedures, have obtained from cholera vibrios a number of deleterious substances which exhibit many of the properties generally associated with endotoxins. The indicator of toxicity for these materials has, however, been limited largely to death following parenteral injection of animals, and association of these endotoxic substances with the clinical manifestations of cholera has been lacking<sup>1</sup>.

More recently, however, De and Ghose<sup>2</sup> and De *et al.*<sup>3</sup> have shown that certain young culture filtrates of *V. cholerae* contain an antigenic and heat-labile substance which produces dilatation of the isolated gut loop; and Oza and Dutta<sup>4</sup> and Finkelstein *et al.*<sup>5</sup> have shown that similar preparations cause a fatal, dehydrating diarrhoea when introduced into the gut lumen of infant rabbits. Both these effects appeared to be specifically neutralized by antisera prepared against the toxic filtrates. Basu Mallik and Ganguli<sup>6</sup> showed that intracutaneous injection of cholera stool filtrates evoked an immediate increase in permeability of skin capillaries in rabbits by the intravenous dye technique. Similar activity, however, was demonstrated to a lesser extent in non-cholera stools; and specific neutralization of the effect was not reported.

The recognition of these heat-labile, extracellular, toxic factors once again suggests the possibility that a 'true' exotoxin may play a significant part in the pathogenesis of cholera, in spite of long-held views to the contrary.

For the work recorded here, stools from cases admitted to the Pakistan-SEATO Cholera Research Laboratory in Dacca, East Pakistan, in 1964, were centrifuged at 10,000 r.p.m. at 5° C for 30 min and the supernatant fluids were passed through 450-mμ 'Millipore' filters. Formed stools were diluted 2- to 10-fold in sterile saline before centrifugation. All stools were cultured for *V. cholerae* as well as other common bacterial enteric pathogens. Filtrates were diluted in sterile saline and injected intracutaneously in 0.1-ml. volumes in partially randomized sites on the backs of albino guinea-pigs or rabbits. Guinea-pigs were prepared by clipping and depilating with barium sulphide paste, while rabbits were clipped only.

The results of the first 56 stools tested in guinea-pigs are shown in Table 1. Stools from 13 out of 20 bacteriologically confirmed cholera cases produced marked induration and erythema beginning 6-8 h after injection, reaching a peak in 18-24 h, receding somewhat by 48 h, but persisting for 4 or 5 days, in both guinea-pigs and rabbits. No induration was produced by any of the filtrates of stools from 33 patients with acute diarrhoea from which *V. cholerae* was not isolated. Of these 33 negative cases, 16 were suffering from a severe watery diarrhoea, similar clinically to cholera, with dehydration and collapse. By replicate titration in both guinea-pigs and rabbits, it was found that the diameter of induration bore a linear relationship to log dose of filtrate, over a range of 6-15 mm. In order roughly to quantitate the activity in each stool, the amount of filtrate in a 0.1-ml.

volume capable of producing induration of 8 mm in diameter at 18-24 h was established as an arbitrary 'induration dose'. All specimens were tested in at least two animals simultaneously, and active cholera stools were used repeatedly for investigation of the properties described here. Most of the same stools were also tested in duplicate in rabbits, and results were essentially identical in both animals.

From three patients with confirmed cholera, stools were collected in the acute purging stage and again after recovery. In one case, both early and late stools were negative. In the other two, stools collected on the first day were strongly positive (> 100 induration doses/ml.), whereas stools collected 57 and 68 days after onset were negative.

The effect of stool filtrates on skin capillary permeability was investigated by the intravenous injection of pontamine sky blue 6XB, 0.12 ml. of a 5 per cent solution/100 g, at varying times before and after the intracutaneous injection of test materials<sup>7,8</sup>. Filtrates capable of evoking induration also caused an increase in permeability of skin capillaries of at least 24 h duration, and the diameter of the blue lesion bore a linear relationship to log dose of filtrate within the range of 5-12 mm. The time-course of increased permeability was determined by injecting filtrates at various intervals followed by intravenous injection of dye when the skin was bearing lesions of different ages. A final injection of filtrate and of saline was given immediately after the dye to determine the immediate permeability effect as well as the effect of trauma. Readings were made 1 h after the injection of dye. Immediately after injection there was a marked increase in capillary permeability followed by recovery within 1 h. During the next few hours the permeability gradually increased again, reaching the maximum diameter, but not maximum intensity, by 8 h. The bluing became more intense between 8 and 18 h and was maximum at 18-24 h. Between 24 and 48 h intensity faded. Induration developed more gradually during the first 24 h; but the peak was the same as for bluing. Permeability returned to normal by 72-96 h, whereas induration gradually receded over a 4-5-day period. Residual induration was palpable at 6-7 days. The time-course of permeability and induration in rabbit skin was essentially the same as that in guinea-pigs. On the basis of these time-course investigations, 18-h lesions were selected for the study of other properties of the stool permeability factor. In all stool filtrates so far examined, increased capillary permeability at 18 h has paralleled the induration response.

Filtrates of *V. cholerae* cultures grown in 5 per cent Difco 'Bacto-Peptone', pH 7.3, as used by De *et al.*<sup>3</sup> for production of cholera enterotoxin, evoked skin lesions indistinguishable from those produced by the skin-factor found in cholera stools. Living vibrios injected intracutaneously failed to evoke any induration or permeability change. De *et al.*<sup>3</sup> showed that the *in vitro* production of cholera enterotoxin active in the ligated rabbit-gut segment was related to surface-volume ratio of the culture medium. This association appears to hold true also in the case of skin-reactive factor. Shallow cultures with surface/volume ratios of 2.5:1 yielded approximately 30 times as much active material as did tube cultures with a ratio of 0.2:1.

The influence of length of incubation on skin-factor production was investigated by titrating permeability factor content of filtrates of two strains of *V. cholerae* grown in shallow cultures in Erlenmeyer flasks (surface/volume ratio of 2.5) for different periods of time at 37° C. The permeability factor was absent at 2 h, detectable at 4 h, reached a maximum titre at 24-48 h and began to wane at 72 h.

The skin reactions evoked by stool and culture filtrates were compared on the same set of guinea-pigs. Time-course of the permeability factor as well as dosage-response

Table 1. TWENTY-FOUR HOURS' INDURATION IN GUINEA-PIGS FOLLOWING INTRACUTANEOUS INJECTION OF STOOL FILTRATES

Source of stool specimen	Induration doses/ml stool filtrate				Positive Total

\* Within 48 h of onset.

curves of induration and the permeability factor of both stool and culture filtrates were indistinguishable qualitatively and quantitatively, suggesting that the two materials are identical.

In order to determine whether substances with similar effect on skin were elaborated by other organisms, the following strains were grown simultaneously in shallow cultures of 5 per cent 'Bacto-Peptone', pH 7.3: *Shigella B*; enteropathogenic *E. coli*; *E. coli*, non-typable; non-cholera vibrio, Heiberg Group II; and *V. cholerae* Ogawa. Neither induration nor change in capillary permeability was produced by intracutaneous injection of undiluted filtrates of cultures of the first four organisms, whereas cholera filtrate gave rise to typical lesions at a dilution of 1:40.

Both the induration-evoking capacity and the permeability factor of both stool and culture filtrates were completely destroyed at 56° C for 30 min. Dialysis of both stool and culture filtrates for 24 h at 5° C. against 0.85 per cent sodium chloride caused a 25-50 per cent loss of skin reactivity. Stool filtrates retained full activity after exposure to trypsin, 100 µg/ml. for 15 min at 37° C at pH 7.0.

The neutralizing capacity of convalescent cholera sera was investigated as follows: acute and convalescent sera from cholera cases were inactivated at 56° C for 30 min. Three-fold serial dilutions of serum were mixed with constant amounts of stool filtrate or culture filtrate and the mixtures were incubated at 37° C for 30 min. The mixtures were injected intracutaneously in guinea-pigs, and intravenous dye was given 18 h later. Convalescent sera from confirmed cholera cases were capable of preventing both the induration and permeability factor effects of both stool filtrate and culture filtrate at a higher dilution than was acute phase serum. The permeability factor-neutralization titres of a number of sera against culture filtrates are set out in Table 2. Titres are expressed as the highest serum dilution which prevented the increase in capillary permeability induced by the standard dose of toxic filtrate. Rises in titre were demonstrable in all cases of confirmed cholera so far tested, but not in human beings given commercial cholera vaccine or in rabbits given living vibrios grown on 1 per cent tryptose slants. Substantial agglutinin titre rises were demonstrated, however, in both the cholera cases and in persons and animals vaccinated with whole organisms. Normal persons and some acute phase sera contained low titres of neutralizing substance. The lowest titres were found in normal rabbits and in the acute phase sera of those cholera patients who showed the highest titres during convalescence.

The foregoing findings indicate that skin-reactive substances found in the stools of cholera patients and in culture filtrates are identical. Moreover, their properties are those of a typical bacterial exotoxin. Hence, the term "skin-toxin" would seem applicable. For the pre-

paration of skin-toxin *in vitro*, the medium and growth conditions are the same as those used for the preparation of the enterotoxin of De. Both are heat-labile. These facts suggest the possibility that the skin-toxin and the enterotoxin are also identical.

At present there is no evidence that the skin-toxin plays a part in the morbid sequence of cholera in man. Skin-toxin could, however, exert a deleterious effect on the gut, perhaps by altering permeability of capillaries in the villi, resulting in the passage of exocoel fluid into extravascular spaces and then into the gut lumen.

Evidence indicates that the skin-toxin is antigenic in man, that it reaches antibody-producing elements during the course of clinical cholera, and that the antibody elaborated behaves like an antitoxin. Moreover, antibody against the skin-toxin does not appear to be evoked by vibrio antigens capable of evoking agglutinins.

## COMPARISON OF FERRITINS FROM NEOPLASTIC AND NON-NEOPLASTIC HUMAN CELLS

By PROF. G. W. RICHTER

Department of Pathology, Cornell University Medical College, New York

IN previous work<sup>1</sup> it was shown that two lines of neoplastic human cells grown *in vitro* synthesize distinctive kinds of ferritin. By electrophoresis in polyacrylamide gels, ferritin from HeLa cells was separated into 3 fractions (α, β, and γ) with mobilities that differed from those of corresponding fractions extracted from human liver cells. Only an α-ferritin was obtained from KB

cells and this had the mobility of the α-ferritin of HeLa cells. These mobilities, like those of other ferritins, are independent of the FeOOH micelles that form the core of the ferritin molecule<sup>2-4</sup>.

We now report results obtained with ferritins synthesized *in vitro* by two strains of embryonic human skin cells, and by HEP-2 carcinoma cells.

Fig. 1. Electrophoretic separations in 5 per cent polyacrylamide gels at pH 6.6. *a*, SK-1 ferritin, separated into five fractions. *b*, Mixture of SK-1 ferritin and ferritin from human liver. Note single  $\alpha$ ,  $\beta$ , etc., fractions. Minor fractions are obscured in this picture.

Fig. 2. Electrophoretic separations in 5 per cent polyacrylamide gels at pH 6.6. *a*, Ferritin from human liver. *b*, Mixture of HEP-2 and liver ferritins. Note separate  $\alpha$ - and  $\beta$ -fractions ( $\gamma$ -bands are obscured). HEP-2 fractions have greater mobilities than corresponding fractions from human liver (spleen, kidney).

A diploid strain of embryonic human skin (M-5) was obtained from Microbiological Associates, Bethesda, Md., after 8 serial passages. We have called this strain SK-1. Its modal chromosome number after 20 further passages has remained 46. Cells of another diploid strain of embryonic human skin, SK-2, were donated by Dr. Albert Kettler of the Public Health Research Institute of New York City. HEP-2 cells were supplied by Microbiological Associates and these were heteroploid. Cultures were grown in Eagle's medium containing 0.01 per cent  $\text{FeSO}_4$ , as previously described<sup>1,4</sup>. Extraction and purification of the ferritins, and the electrophoretic and serological analyses were done as already described<sup>1</sup>. Although equivalent results were obtained when electrophoretic separations were carried out at diverse pH values (4.8–8.6), a pH of 6.6 was most satisfactory. After separation in polyacrylamide gels at pH 6.6, the fractions were either stained by the Prussian blue method for ferric iron or with amidoschwartz for protein. In separate experiments, the fractions were eluted, and checked for the presence of ferritin by electron microscopy<sup>1,8</sup>.

Typical findings are shown in Fig. 1, where it can be seen that SK-1 ferritin was resolved into at least three fractions, identical in mobility with the  $\alpha$ -,  $\beta$ - and  $\gamma$ -fractions of human livers or spleens. SK-2 cells yielded three fractions that had mobilities exactly like those of the corresponding three SK-1 fractions. By contrast, HEP-2 cells produced  $\alpha$ -,  $\beta$ - and  $\gamma$ -fractions with mobilities that were greater at (pH 6.6) than those of the corresponding fractions from SK-1 cells, SK-2 cells or from livers and spleens (Fig. 2). Moreover, the mobilities of the HEP-2  $\alpha$ -,  $\beta$ - and  $\gamma$ -fractions were the same as those of the corresponding three fractions from HeLa cells.

It was noted previously that in double diffusion tests HeLa and KB ferritins had the serological specificities of ferritin from human livers and spleens, when tested with rabbit antisera specific for splenic and hepatic ferritin<sup>1</sup>. Similar precipitin tests in gels have revealed no serological differences between SK-1 ferritin, SK-2

Fig. 3. Results of precipitin tests in agar gels. *a*, Comparison of SK-1 (SK), HeLa (He), and KB (KB) ferritins with ferritin from human liver (M). Rabbit antiserum (AM) to M was used in this test. Note that precipitin bands in front of each well are joined completely to those in front of neighbouring well(s). No serological differences between antigens were revealed by this or by similar tests. *b*, Comparison of HEP-2 ferritin (Hp) with ferritins from human liver (M) and from horse spleen (H). AM-1: rabbit antiserum against M. AM-2: rabbit antiserum against another preparation of human ferritin (from spleen). AH: rabbit antiserum against H. Note that Hp and M gave reactions of identity when tested with AM-1 or AM-2. There is a weak band between H and AM-2. No band was formed between Hp and AH, but this may have been due to insufficient concentration of Hp since—as can be seen—M reacted only weakly with AH in this test.

Fig. 4. Electrophoretic mobilities of various ferritins relative to each other. Five per cent polyacrylamide gels at pH 6.6.

ferritin, HEP-2 ferritin and the ferritin from human liver and spleen (Fig. 3a and b). Thus, all these materials gave reactions of identity when tested with rabbit antisera to unfractionated, highly purified human ferritin.

The results obtained with various sorts of ferritin by means of electrophoresis in polyacrylamide gels are summarized in Fig. 4. The evidence reveals a pattern in which neoplastic cells are separated from non-neoplastic cells (or tissues), but tests of ferritins produced by tumours *in vivo* are needed to evaluate the significance of these results in relation to neoplasia. While the synthesis of

distinctive ferritins in neoplastic cells may indicate potentialities that are unrelated to neoplasia, it is obviously important to investigate the possibility that there is a link.

## EFFECT OF CARRIER-GAS ON GAS-LIQUID PARTITION

By P. A. SEWELL and DR. R. STOCK\*

College of Technology, Liverpool

IN gas-liquid chromatography the carrier-gas is normally almost completely insoluble in the stationary phase, but it may affect the solubility of another gas or vapour by altering its fugacity. Different carrier-gases will affect the solubility of a given vapour to different extents, and this has been shown in gas-chromatography experiments utilizing capillary columns, by Desty, Goldup, Luckhurst and Swanton<sup>1</sup>. These authors also derived an equation relating the  $k'$  factor of a gas chromatographic column (the ratio of the liquid phase capacity to the gas phase capacity) to the mean absolute column pressure,  $\bar{p}$ , and the second virial coefficient,  $B_{12}$ , accounting for interactions between unlike molecules of the mixed gases. From a plot of  $\log k'$  against  $\bar{p}$  the activity coefficient at infinite dilution of a solute,  $\gamma_2^\infty$ , may be estimated without the need to correct for carrier-gas/solute interactions. Values of  $B_{12}$  have also been calculated from the gas chromatography experiments and good agreement has been obtained with values calculated from the Beattie and Bridgeman formula<sup>2</sup>.

The solubility of the vapours of chloromethanes in squalane and dimonyl phthalate have been measured by Freeguard and Stock<sup>3</sup> by a static technique involving a McBain-type spring balance. In the present work we have been concerned to measure directly, by a similar static technique, the effect of an inert carrier-gas (for the most part nitrogen) on the solubility of these vapours. From these measurements it should then be possible to obtain values of  $B_{12}$ , and verify directly the equation of Desty *et al.*<sup>1</sup>:

$$\log k' = A + \frac{\bar{p}}{2 \cdot 303 RT} (2B_{12} - v_2^\infty)$$

where  $v_2^\infty$  is the molar volume of the solute at temperature  $T$ .

The static method has the advantage that the contribution of adsorption and solubility of the carrier-gas can be determined easily.

A McBain-type balance similar to that described by Freeguard and Stock<sup>3</sup> was used, but the system was modified so that thorough mixing of the two gases (absorbate and inert gas) was achieved, and so that gases could be admitted to the system without loss of absorbate vapour already present, by back-diffusion.

To ensure thorough mixing of the gases a glass 'loop', surrounded by a water-jacket and maintained at the same temperature as the balance case, was connected to the top and bottom extremities of the balance case. This permitted free circulation of the gases in the system, and an actual flow of gas was promoted by means of a glass paddle, in which was embedded a small magnet, and which was made to revolve at high speed by means of a magnetic stirrer. This device was found to be effective even when the total pressure in the system was only about 2 or 3 cm.

To prevent back-diffusion when adding fresh charges of gas, a doser technique was employed, that is, additional gas was displaced into the system by means of a mercury piston, operating through a series of valves. In practice this procedure was only necessary when quite high pressures of gas were already present in the system.

The inert gas was dried by passing it over an activated molecular sieve (Linde 5A). The involatile liquids used were squalane and dimonyl phthalate coated on 'Celite', the liquid loading being about 30 per cent by weight. An experiment was performed using squalane alone, but equilibrium times were so long (cf. Freeguard and Stock<sup>3</sup>) that other measurements using involatile liquids alone were not attempted.

All the experiments described here were carried out at 30° C using carbon tetrachloride as the absorbate, and the following procedure was adopted to measure the effect of the inert gas on the absorption of this vapour. The solid support and involatile liquid were contained in a light glass bucket and suspended by a fused quartz spring (extension approximately 1 m per g) and degassed to better than 10<sup>-4</sup> mm of mercury. A charge of carbon tetrachloride vapour was then admitted and the increase in weight of the sample noted at equilibrium. Inert gas was then admitted, the gases were thoroughly mixed and allowed to equilibrate and the change in weight of the sample was noted. Further charges of inert gas were added in a similar way. It was ascertained that the uptake of the inert gas was negligible by performing similar experiments in the absence of the absorbate. The change in weight of the sample, after correcting for buoyancy, was therefore due to absorption or desorption of the solute caused by interactions in the gas phase between the solute and the inert gas.

It was at first thought that the presence of the inert gas might so retard the equilibration of the absorbate vapour with its solution in the involatile liquid that it would prove impossible or very difficult to determine when equilibrium had been attained, hence a preliminary experiment was carried out in which a charge of nitrogen was admitted to the previously evacuated balance case until a pressure of about 20 cm was reached. Charges of carbon tetrachloride vapour were then admitted and an isotherm measured in the usual way. The results were presented graphically by plotting the increase in weight of the sample against the apparent pressure of the carbon tetrachloride, that is,  $(P - p_1)$ , where  $P$  was the total pressure in the system and  $p_1$  was the pressure of nitrogen. The curve thus obtained should be identical with that obtained when performing the experiment in the absence of nitrogen, since the term  $(P - p_1)$  takes into account interactions between the carbon tetrachloride and the nitrogen (assuming negligible effect on the fugacity of the nitrogen by the carbon tetrachloride). Good agreement between the curves was found,

\*Address from September 1, 1965, Department of Chemistry and Biology, Nottingham Regional College of Technology.

suggesting that equilibrium was established under the experimental conditions.

Some results using squalane as the involatile liquid are presented graphically in Figs. 1 and 2. In Fig. 1 each curve shows the change in weight of the sample for a fixed pressure of carbon tetrachloride but varying pressure of nitrogen. In practice the pressure of carbon tetrachloride did not remain constant throughout each experiment because of the small amount desorbed by the sample on admitting nitrogen. The volume of the system was so large, however, that the increase in pressure due to desorption was considered negligible. In all the experiments desorption of carbon tetrachloride was observed when either nitrogen or carbon dioxide was added to the system, regardless of the initial pressure of the absorbate or the pressure of the inert gas. This is consistent with predictions based on the theory of corresponding states<sup>4</sup>.

In Fig. 2 absorption isotherms of carbon tetrachloride in squalane are shown. Curve 1, showing the largest

Fig. 1. Variation in absorption of carbon tetrachloride by squalane at 30°C with increasing pressure of nitrogen

Fig. 2. Absorption isotherms of carbon tetrachloride in squalane at 30°C, effect of nitrogen. Curve 1, pure  $\text{CCl}_4$ ; 2, 10 cm  $\text{N}_2$ ; 3, 30 cm  $\text{N}_2$ ; 4, 60 cm  $\text{N}_2$ .

uptake of vapour, is the isotherm measured in the absence of an inert gas. Curves 2, 3, and 4 are isotherms measured at 10, 30, and 50 cm of nitrogen respectively. They show that the higher the pressure of nitrogen, the greater the depression of the isotherm. Points for curves 2, 3, and 4 were extracted from the curves in Fig. 1, and some additional curves not shown.

It is possible to calculate  $B_{11}$  from the above results in the following way. If the absorption by the involatile liquid is plotted against the fugacity of the absorbate then all points should fall on the same isotherm, regardless of the amount of inert gas present. The isotherms in Fig. 2 show the plot of absorption against pressure, therefore horizontal lines drawn through these curves join points of constant fugacity of carbon tetrachloride vapour. The fugacity,  $p_1^*$ , of the pure vapour at pressure  $p_1$  is given<sup>5</sup> by:

$$\ln p_1^* = \ln p_1 + \frac{B_{11} \cdot p_1}{RT} \quad (1)$$

where  $B_{11}$  is the second virial coefficient<sup>6</sup> for the pure vapour. In the presence of an inert gas, the fugacity of the vapour at pressure  $p_1'$  is given<sup>5</sup> by:

$$\ln p_1'^* = \ln p_1' + \frac{P}{RT} [B_{11} - (1-y)(B_{11} - 2B_{12} + B_{22})] \quad (2)$$

where  $P$  is the total pressure;  $B_{11}$  is the second virial coefficient of the inert gas;  $y$  is the mole fraction of the solute in the gas phase. Hence when the fugacities are equal the following expression for  $B_{11}$  is obtained from equations 1 and 2:

$$B_{11} = \frac{1}{2}(B_{11} + B_{22}) - \left[ RT \ln \frac{p_1'}{p_1} + B_{22}(P - p_1) \right] / 2P(1-y) \quad (3)$$

It is interesting to note that this is the Lewis-Randall approximation with an additional term.

In calculating results for  $B_{11}$  no allowance was made in the pressure for desorption of carbon tetrachloride from the sample, as already mentioned, hence  $p_1'$  was taken as the initial pressure of absorbate before admitting nitrogen, and  $y$  was assumed to be  $p_1'/P$ . In equation 3 the measured quantities are  $P$  and  $p_1'$ ;  $p_1$ , the pressure of pure absorbate which would give the same uptake in the absence of inert gas, was either taken from the appropriate isotherm, or calculated from an empirical equation for the isotherm, known to give a good fit over the narrow range of pressures under consideration. As might be expected, the latter method gave more consistent results.

The value of  $B_{11}$  for the system: carbon tetrachloride/nitrogen at 30°C calculated from the corresponding states theory of Guggenheim and McGlashan<sup>4</sup> is approximately -158. Values of  $B_{11}$  obtained by the above method ranged from about -226 to about -10,000. Values should remain constant regardless of pressure, whereas in the present work  $B_{11}$  usually approached the value given by the corresponding states theory as the pressure of nitrogen increased. These discrepancies may be accounted for in part by the method of calculation; slight variations in the term  $\ln p_1'/p_1$  in equation 3 are greatly magnified and seriously affect the value of  $B_{11}$ . On the other hand, the curves in Figs. 1 and 2 show the expected reduction of the fugacity of carbon tetrachloride by nitrogen and there is a measure of consistency in the curves not apparent in the values of  $B_{11}$ . Similar results were obtained with the systems carbon tetrachloride/nitrogen/dimethyl phthalate and carbon tetrachloride/carbon dioxide/squalane.

## LETTERS TO THE EDITOR

## GUIDANCE WHEN ORDERING REPRINTS

Reprints of articles, letters, etc., should be ordered by authors on order forms sent with galley proofs, and returned with proofs to printers. These should be accompanied by remittance.

Authors should endeavour to ensure that adequate supplies are ordered in the first instance and, when more than one author is concerned, total requirements of all authors should be sent as one order.

If in Great Britain, official orders from organizations or institutions will be accepted without prior remittance; but, owing to cost of clerical work involved, orders received from overseas unaccompanied by remittance cannot be accepted.

Minimum time for despatch is approximately four weeks after the article has been published. Reprints are sent by parcel post (surface mail) unless special arrangements are made by the author.

Any correspondence in connexion with reprints must give Title, Author, Article Number and, if known, the date of publication. All communications regarding reprints should be sent direct to the printers, whose address is as follows:

Fisher, Knight and Co., Ltd.,  
Gainsborough Press,  
St. Albans,  
Hertfordshire,  
England.

## PHYSICS

## Effect of Pressure on the Viscosity of Water

An accurate knowledge of the viscosity of water as a function of pressure is important in the interpretation of the effect of pressure on the electrical conductance of aqueous electrolytes. For this reason we have recently measured the viscosity of water at pressures up to 10,000 kg/cm<sup>2</sup> relative to that at atmospheric pressure over the temperature range 2.2° C–100° C (ref. 1). The only other measurements at pressures greater than 900 kg/cm<sup>2</sup> are those of Bridgman<sup>2</sup>; but these are of limited accuracy because of the experimental difficulties he encountered when he used his viscometer to investigate water.

Fig. 1. Relative viscosity of water

Fig. 2. Absolute viscosity of water

The viscometer used in our investigation is of the falling-body type; it consists of a stainless steel tube containing two sinkers, one of high and the other of low density. Measurements are made by inverting the pressure vessel containing the viscometer and timing the fall of each sinker through the fluid separately by means of an electronic timer actuated by an electrical induction system within the vessel. The technique is novel in that the use of two sinkers permits measurements to be made of the density of the fluid as well as the viscosity.

Comparison of the unsmoothed experimental results for the relative viscosity of water given in Fig. 1 with those obtained by Bridgman shows that the deviations do not conform to a general pattern. At 10° C his results are

lower than ours whereas at the other temperatures they are higher, the discrepancy at 75° C and 10,000 kg/cm<sup>2</sup> being as large as 25 per cent. The agreement with low-pressure data<sup>3-5</sup> is generally good and within the experimental error of our observations, which is estimated to be  $\pm 1$  per cent. Interpolation of our results shows that the temperature at which the initial pressure coefficient is zero is 33.5° C. Values of the absolute viscosity of water given in Fig. 2 have been calculated from our results with the aid of Bingham and Jackson's results for the viscosity of water at atmospheric pressure<sup>7</sup>.

We thank the Council for Scientific and Industrial Research for providing funds to enable us to build the high-pressure viscometer.

### Calculations with Two Nearly Equal Quantities

A FAMILIAR experimental problem arises when two quantities of about equal magnitude are measured, and a third quantity equal to the difference between the two is to be calculated. The relative error in the calculated result can be intolerably high. An example of such a situation is the measurement of airglow radiations from the upper atmosphere in the presence of Rayleigh scattering from the lower atmosphere, where the strength of the desired signal may be small compared with that of the background. Initial measurements of airglow which we made with a simple photometer resulted in plots of calculated airglow intensity versus time with such large fluctuations that no interpretation was possible.

In these circumstances, information can be extracted with greater reliability by taking ratios rather than differences. Taking the example referred to here, let the intensity of the background be  $B$ , and that of the signal-plus-background be  $S + B$ . If each is measured by counting the total number of photons arriving in a standard time-interval, then the standard deviations,  $E_B$  and  $E_{S+B}$ , are  $\sqrt{B}$  and  $\sqrt{S+B}$ , respectively. We wish to compare the relative errors in  $\bar{S} = (S+B) - B$ , and  $R = (S+B)/B$ , denoted by  $e_S$  and  $e_R$ , respectively. It is easily shown that in the situation being considered:

$$e_S = \sqrt{\frac{S+2B}{S^2}}$$

$$e_R = \sqrt{\frac{S+2B}{B(S+B)}}, \text{ and}$$

$$\frac{e_S}{e_R} = \sqrt{\frac{B(S+B)}{S^2}}$$

It is of interest to note that while the accuracies of both  $S$  and  $R$  can be improved by increasing the counting time, the ratio of these accuracies is independent of counting time.

A plot of  $(e_S/e_R)$  versus  $R$  is shown in Fig. 1. The ratio of errors has the value unity at  $R = 2.6$ , or  $S = 1.6B$ . For  $S < 1.6B$ , the advantage lies with taking the ratio. This is consistent with my finding that plots of  $R$  calculated from my data had considerably less scatter than plots of  $S$  calculated from the same data.

Fig. 1. Relative errors in  $S$  and  $R$ .

## GEOLOGY

### An Interglacial Soil at Teindland, Morayshire

RECENTLY a fairly well preserved podsol was found buried beneath glacial deposits at Teindland, Morayshire (map ref. O.S. 299586). Briefly, the section shows at the top a semi-podsol developed in 6-8 ft. of sandy till and outwash gravel overlying a fossil iron podsol developed in glacio-fluvial outwash. The upper part of the buried soil which originally was the organic and leached layers has been transformed to thin bands of black, dark grey and light grey material. This banding has most likely been produced by solifluxion.

The black bands were sampled in September 1963 and found to contain 1.44 per cent organic carbon. A sample submitted to the National Physical Laboratory (reference NPL-78) for radiocarbon measurement was dated to  $28,140 \pm 480$  and  $-450$  years (B.P.), where the uncertainties quoted are derived from one standard deviation of the activity measurement. The age must be regarded as a minimum, since the nature of the sample precluded alkali pretreatment.

Hence the history of the site may be reconstructed as follows: (1) Glaciation (Riss ?) followed by the deposition of glaciofluvial deposits. (2) Soil formation in the above deposits to produce a well-developed iron podsol. (3) Periglacial conditions which caused disturbance and solifluxion of the surface layers. (4) A second period of glaciation (Würm ?) during which the soil was buried with till and outwash. (5) Holocene pedogenesis in the upper part of the Würm deposits.

The buried soil is more leached and differentiated than the contemporary one formed above it at the present surface. Therefore, it was differentiated either over a longer or over a shorter, more intense period of soil formation than the holocene. If the latter, the buried soil could be of interstadial age. However, it is doubtful if such conditions existed during the Würm interstadials, and a more likely explanation is that it developed as a result of long and continuous leaching during the last interglacial period.

The age of the organic matter merely indicates the time at which the soil was buried. It would seem that it lay outside the limits of Würm glaciation for a considerable time undergoing solifluxion and vegetative change, and that only during the middle to late Würm did the ice advance sufficiently to bury this soil.

I thank Mr. A. C. B. Hutcheon of this Department for the determinations of organic carbon, and the National Physical Laboratory for the radiocarbon measurements and age estimate provided in report C.65 of August 27, 1964.

University of Aberdeen.

### A Possible Main Würm Glaciation in West Pembrokeshire

Two carbon-14 age determinations from marine mollusc fragments in glacial outwash in Pembrokeshire have indicated that the last glaciation of West Wales from the Irish Sea probably occurred within the past 38,000 years.

At Mullock Bridge (grid ref: SM 811080), just north of the mouth of Milford Haven, a large gravel-pit has been cut into a terrace of fluvi-glacial outwash material. The locality lies within the area of so-called 'Older Drift' in West Wales (Fig. 1)<sup>1</sup>. The terrace has a maximum surface altitude of 100 ft. O.D., and in the sides of the pit at least 25 ft. of current-bedded sands are visible; these sands appear to have been deposited deltaically, in the sea or in a pro-glacial lake. The sands are interbedded with, and overlain by, fine shelly gravels, which are in turn overlain by coarse torrential outwash. In parts of the gravel-pit unleached shelly gravels are seen within 3 ft. of the terrace surface. The northern part of this surface has a patchy covering of stony and gravelly till,

beneath which the shelly gravels are severely contorted. It seems, therefore, that the ice-front may have been in the vicinity of Mullock Bridge during the deposition of the gravels, and later advanced for an unknown distance across the outwash terrace. A sample of about 400 g of well-preserved and solid fragments of marine molluscs from shelly gravels beneath the till has been dated at  $37,960 \pm 1,700$  years B.P. (NPL-80).

Eighteen miles to the north a small gravel-pit has been cut into shelly outwash gravels at Tre-llys (grid ref.: SM 898349), near the north Pembrokeshire coast. The gravels, which lie at an altitude of 200 ft. O.D., have a hummocky surface expression, and were considered by Charlesworth<sup>2</sup> to be part of the 'South Wales End-moraine'. As at Mullock Bridge, shelly gravels are irregularly interbedded with sands in the pit; they are generally overlain by about 6 ft. of coarse torrential outwash, but in places shelly gravels occur within 4 ft. of the ground surface. In places the outwash contains severe slump features and contortions, and in view of the interbedding of small till masses it may be proposed that the deposits were laid down in an ice-contact environment during the wastage of an ice-sheet. More than 300 g of marine mollusc fragments from this pit have been dated at  $37,310 \pm 1,515$  years B.P. (NPL-97).

The shell fragments collected at each locality for carbon-14 dating represent a wide range of environments, and therefore constitute a 'mixed' fauna<sup>3</sup>. So far as could be ascertained, no Crag species were included in the collections, but nevertheless the occurrence of the cold indicators *Trophonopsis clathratus* (L) and *Chlamys islandica* (Müller) alongside species found in Pembrokeshire waters to-day may indicate that the molluscs vary greatly in age and provenance. The carbon-14 dates must be considered as mean dates, and the possibility borne in mind that many shells older than about 38,000 years B.P. may be mixed with shells which lived after that date.

There is no evidence that either sample was contaminated. Laboratory pre-treatment included the rejection of apparently weathered shell fragments and the removal by leaching of the outer third of the shells in each test sample. The middle and inner thirds of each test sample were dated separately, with almost identical results.

The widespread occurrence of marine molluscs at Mullock Bridge and Tre-llys indicates that the ice-sheet which incorporated the molluscs and later deposited the shelly outwash and gravelly till probably moved across western Pembrokeshire from the north and north-west. This suggestion is supported by the presence of erratics from the St. David's Peninsula in the gravels at Mullock Bridge. There appears to be little doubt that the ice-sheet was a true Irish Sea ice-sheet. If some of the dated shells lived in the Irish Sea within the past 38,000 years, then it follows that the last glaciation of West Wales occurred even more recently.

This dating seems to contradict several previously published opinions concerning the age relationships of drifts around the Irish Sea. Mitchell<sup>4</sup> and Synge<sup>5</sup> consider that all the glacial drifts of West Wales are the equivalent in age of the Eastern General till of Ireland, which in turn they correlate with the Gipping till of East Anglia. They consider that the maximum extension of the Irish Sea ice during the Last Glaciation is represented by the Midland General-Clynnog Fawr morainic limit, which passes from the Screen Hills of Wexford to the Llyn Peninsula (Fig. 1). Alternatively Charlesworth<sup>2</sup>, while agreeing that most of the till in West Wales is of 'Older Drift' age, has proposed a limit for the ice of the Last Glaciation at the so-called 'South Wales End-moraine' of north Pembrokeshire. On the other hand, the evidence from Mullock Bridge and Tre-llys indicates that the Irish Sea ice of the Last Glaciation probably extended much farther south, and over-rode the whole of western Pembrokeshire. Thus it appears that neither the Midland

Fig. 1. Current ideas concerning the glaciation of Wales and the southern Irish Sea Basin

General-Clynnog Fawr moraine nor the South Wales End-moraine can be identified as a true terminal feature, unless it represents minor re-advances or retreat stages during deglaciation.

The Mullock Bridge and Tre-llys dates, themselves almost identical, are markedly similar to radiocarbon dates from Upton Warren (41,900 years B.P.) and Fladbury (38,000 years B.P.) in the Midlands. At the latter localities faunal and floral remains record the presence of fluctuating interstadial conditions, and likewise the marine mollusc assemblages in the Pembrokeshire outwash gravels indicate that boreal conditions probably prevailed at about this time. The Pembrokeshire evidence lends support to the suggestion of Coope, Shotton and Strachan<sup>7</sup> that interstadial conditions in Britain around 42,000–38,000 B.P. may be correlated with part of the Middle Würm period of fluctuating sub-arctic and boreal climates proposed for Northern Europe by Gross<sup>8</sup>.

Concerning the absolute dating of the southernmost advance of the Irish Sea ice during the Würm, two recent suggestions have been made. Coope, Shotton and Strachan consider that this advance occurred between 57,000 and 42,000 years ago; this is based on the interpretation of radio-carbon dated beds at Chelford<sup>9</sup>, Upton Warren, and Fladbury, and their relationships with the Severn-Avon terraces and the Midland tills. Similarly, Bowen<sup>10</sup> has proposed that the 'Main Welsh Glaciation' of South Wales was the equivalent of the European Early Würm, followed by a smaller 'Welsh readvance' during the Main Würm. On the other hand, Penny<sup>11</sup> has suggested that the maximum ice advance of the Last Glaciation throughout Britain was the approximate equivalent in time of the European Main Würm glaciation, which was most extensive between 25,000 years B.P. and 17,000 years B.P.<sup>12</sup>

The evidence from Pembrokeshire suggests that there was an extensive glaciation in Western Britain later than 38,000 years B.P., and it therefore appears to provide support for Mr. Penny's suggestion. However, the possibility remains that an even more extensive glaciation could have occurred before that date, perhaps during the Early Würm. Some recent work in north-east Scotland by Dr. E. A. FitzPatrick and D. E. Sugden has a bearing on this problem. Dr. FitzPatrick<sup>13</sup> has suggested on the basis of a recently obtained carbon-14 date from Tiendland, near Elgin, that non-glacial conditions persisted in north-east Scotland from the beginning of the Würm until 28,000 years B.P., and this is supported by traces of a long phase of corrie glaciation in the Cairngorm Mountains prior to the development of the Main Würm ice-sheet<sup>14</sup>. In view of this evidence it is difficult to envisage an Early Würm glaciation which could have extended as far south as the approaches of the Bristol Channel.

In Scotland and in the northern Irish Sea basin<sup>15</sup> there are signs of an extensive glaciation after 28,000 years B.P., which correlates with the European Main Würm maximum. In view of the apparent synchronicity of events in Britain and Northern Europe, it seems reasonable to propose that the Last Glaciation of West Wales was a part of this Main Würm glaciation. Whether or not the foregoing correlations are correct, the carbon-14 dates from Pembrokeshire strongly suggest a widespread glaciation of Western Britain some time after 38,000 years B.P., and the possibility emerges that other landscapes south of the Newer Drift limit may have been glaciated during this glaciation.

It is hoped that the evidence for the points made here will soon be published in a more detailed analysis of the Mullock Bridge exposure. So far, no reliable clue has been obtained as to the absolute age of the Irish Sea till of West Wales and Eastern Ireland; stratigraphic evidence suggests that the till may be no older than the dated shelly outwash, but this may be misleading. Two carbon-14 age determinations on organic material from this till may soon be completed, and perhaps it will then be possible to

suggest a tentative chronology for the Late Pleistocene events of the southern Irish Sea basin.

I thank Dr. Marjorie Sweeting, Miss Gillian Groom and Mr. D. F. W. Baden-Powell for their advice. I also thank the National Physical Laboratory for the radio-carbon dating of the Pembrokeshire samples.

### Seed-bearing *Ottokaria*-like Fructifications from India

ALTHOUGH Plumstead<sup>1-4</sup> has described a number of male, female or bisexual fructifications obviously attached to fertile leaves of *Glossopteris*, *Gangamopteris* and *Palaeovittaria*, not a single specimen among them shows clearly determinable seeds or sporangia. *Glossopteris*-like fertile leaves, called *Lidgetttonia*<sup>5</sup>, were found closely associated with bodies which appear to be very similar to undoubted seeds and sporangia described by Pant<sup>6</sup> and Pant and Nautiyal<sup>7</sup>. Nevertheless, no one has so far reported any indubitable seeds or sporangia actually borne on attached fructifications of *Glossopteris*. Pant<sup>6</sup> has, however, described *Arborella*-type sporangia attached to certain disks which are associated with *Glossopteris* leaves but, so far, seeds have not been found attached even on isolated fructifications occurring in association with *Glossopteris*. The present seed-bearing *Ottokaria*-like fructifications from the Lower Gondwanas of Bihar are therefore of extraordinary interest.

In all, four fructifications have been found, two of which are illustrated in Figs. 1–5. One of them (Figs. 1, 2) is apparently attached, by means of a slender stalk, to a scale or *Gangamopteris*-like leaf. Some of the veins in the leaf are distinctly anastomosing (Fig. 3) but it shows no midrib, at least in the apical part (the lower part is not seen). The stalk of the head appears to be coming out from its side but it is presumably attached to the bottom of the head which is in contact with the rock. The head bears a number of laterally flattened oval seeds at the periphery and its upper face shows vague rounded scars in the centre. We believe that the disk-like head originally bore seeds all over the face now exposed. During fossilization, when the whole structure was compressed, seeds borne in the centre stood erect (for want of space) and therefore became rounded due to antero-posterior flattening, while seeds near the margin were compressed laterally and appear oval. Some marginal seeds in this specimen are flanked by sterile wing-like structures on either side. The specimen also shows, lying over the stalk of the fructification, a detached seed, exactly like the attached ones but without any flanking sterile tissue. The second specimen, illustrated in Figs. 4 and 5, shows a fructification lying near the apex of a *Glossopteris* leaf but not attached to it. The associated leaf is similar to *Glossopteris fibrosa* in having narrow meshes and fibres between veins. This second fructification apparently shows a few veins in its stalk which run up to the centre of the head and from there branch and spread out on its

surface like the veins of *Ottokaria beugaleensis*<sup>1,10</sup> or *Sourum*. Attached seeds are also seen projecting from the periphery of this specimen. Some sterile tissue is seen by the side of seeds even here. Carbonaceous material of the fructifications is preserved in all our specimens. The seeds are sessile and orthotropous. They are ovoid in shape, having a more tapering micropylar end and a broader rounded base. Their surface shows elongated rectangular cells in longitudinal rows. The external form of these seeds is therefore quite like that of some seeds described by Pant<sup>7</sup> and Pant and Nautiyal<sup>8</sup>. Like the detached seeds of these authors, the attached seeds in our fructifications are either found compressed (Figs. 1 and 2) or mud-filled (Figs. 4 and 5). We regard the foregoing two types of fructifications as representing two views of the same type of structure which had a slender stalk attached on the sterile back of a terminal flat or slightly convex side of a peltate or semipeltate disk. The back of the disk also shows veins radiating round the stalk. On the front (possibly concave) side of the disk were attached a number of seeds. The sterile tissue seen between the seeds may represent their wings, sterile flesh, cupules or interseminal bracts. If these were bract-like structures they could have been of the same nature as the so-called 'male bracts' of *Sourum*<sup>3</sup>. However, as preserved, our fructifications could never be regarded as bivalved and there is no evidence to show that they were bisexual. We believe that, contrary to Plumstead's interpretation, the fructifications described by her may, similarly, not be bivalved. As they appear to us, our multi-ovulate fructifications are rather like the detached microsporangiate disks described by Pant<sup>7</sup>. However, in place of the seeds in the present female disks, the male disks bear numerous *Arborella*-type of sporangia which contained two winged spores of *Striatites* type. Examination of detached seeds like those borne by our disks has shown that they were pollinated by similar *Striatites* type of pollen grains<sup>11</sup>. We are therefore in-

clined to think that *Glossopteris* was a gymnosperm the fertile leaves of which bore separate male and female disk-like fructifications. The general organization of the male (and even female) disks could not have been very different from that of *Potonia*. Possibly, the female disks of *Glossopteris* could be compared with the multi-ovulate cupules of *Calathospermum* in the same manner as we can compare the flat disks of *Dorstenia* with the hypanthodia of *Ficus*. Of course the disks and cupules of the Moraceae are sympatric developments of inflorescences bearing flowers, quite unlike the ovule bearing disks and cupules of *Glossopteridaceae* and *Calathospermum*.

### Age of the New Red Sandstone in South Devonshire

RADIOMETRIC dating of the Exeter Volcanic Series (the Exeter Traps) recently gave ages of  $270 \pm 6$  m.y. and  $281 \pm 11$  m.y. for the Killerton mica-lamprophyre (minette)<sup>1</sup> and the Dunchideock basalt<sup>2</sup> respectively. These and other extruded masses of the Series are interbedded with breccias and sandstones of the New Red Sandstone both north and south of Exeter, and as far west as Hatherleigh; new evidence is thus provided of the age of the strata.

The main intrusive event of the Dartmoor granite is dated at 295 m.y. (ref. 3), the paroxysmal phase of the Variscan Orogeny being regarded as preceding this by only a short time<sup>4</sup>. Smith<sup>5</sup> puts the Permo-Carboniferous boundary at 280 m.y.

Definition of stratigraphic units in the New Red Sandstone in the coast section from Paignton to Seaton is in progress. The succession consists of over 9,000 ft. (2.75 km) of unmetamorphosed red breccias, sandstones and siltstones, lying unconformably on deformed Devonian and Carboniferous rocks. A relief mountainous topography is shown by the unconformity, and the New Red formations overlap progressively northwards. Two sequences can be distinguished in the succession, of which the lower and thinner one is recognized only in the Torquay district. They are separated by a small but clear angular unconformity recording contemporaneous tectonic activity.

The age of the New Red Sandstone has long been a subject of discussion. The only fossils are reptile remains (Triassic) high in the succession<sup>6</sup>, an unrecognizable plant, and some trace fossils; consequently, lithological similarities have been urged as evidence of age. Thus Irving<sup>7</sup> argued that the Budleigh Salterton Pebble Bed formed the base of the Triassic by analogy with the succession in the Midlands, a conclusion accepted with reservation by Ussher<sup>8</sup>. The Permian age of the strata beneath had been postulated by Murchison<sup>9</sup>, and was supported by the presence of the lavas which were compared with similar types in the Permian of Germany<sup>10</sup>.

Figs. 1-5 1, A seed-bearing *Ottokaria*-like head with the seminiferous face exposed. The stalk is apparently attached to a scale or *Glossopteris*-like leaf. A detached seed is seen lying over the slender stalk ( $\times 0.1$ ); Fig. 2, Disk in Fig. 1 more magnified to show wing-like sterile tissue flanking some seeds ( $\times 0.2-7$ ); Fig. 3, Portion of leaf in Fig. 1 more magnified to show vein anastomoses ( $\times 0.8-4$ ); Fig. 4, A detached seed-bearing fructification lying by the side of a *Glossopteris* leaf. The specimen shows the back of the disk and seeds projecting from margin ( $\times 0.1-4$ ); Fig. 5, Fructification in Fig. 4 more magnified to show details ( $\times 0.2-7$ ); one of the vein anastomoses; *ist*, interseminal tissue; *p*, stalk; *s*, seed

# GEOPHYSICS

## Significance of Strontium Isotope Ratios in Theories of Carbonatite Genesis

The radiometric evidence now invites a re-appraisal of the age question, requiring a correlation of the lava horizons with the succession on the coast. South of Exeter, field work indicates that the Dunchideock lava lies at a level equivalent to the lower beds of the upper sequence, as suggested by Ussher<sup>11</sup>. Marker horizons are lacking, however, and such correlation cannot be definite. Although fragments of the Exeter lavas have not been positively identified in the rocks of the coast section, they are common in the Crediton Valley in New Red strata above those associated with the extrusions. The succession of fragment facies established by Hutchins<sup>12</sup> in that area can be traced to the coast section<sup>13,14</sup>, and this also suggests that the lavas were contemporaneous with the lower beds of the upper sequence, probably the basal limestone breccias. Fragments and boulders of dominantly acidic volcanic and dyke rocks are abundant in both lower and upper sequences, but are not closely related to the Exeter lavas. As they occur in sediments that show evidence of derivation from the direction of Dartmoor, they presumably result from volcanicity on the roof of the granite pluton<sup>15</sup>, predating the lowest visible New Red deposits, and probably contemporaneous with the intrusion.

From the available evidence, and accepting the dates for the Exeter lavas and the Permo-Carboniferous boundary, it is probable that: (a) the lower sequence at Torquay and the lower beds (Cadbury Beds<sup>12</sup>) in the Crediton Valley are of Upper Carboniferous (Stephanian) age; (b) minor tectonic movements occurred at or near the end of the Carboniferous Period in the region. Later movements affecting the New Red Sandstone appear to be Cretaceous (probably Aptian) in age, since similar movements affected strata up to Wealden near Weymouth<sup>16</sup>, but not the Upper Greensand of the Haldon Hills. Mid-Tertiary wrench faulting also affected the region<sup>17</sup>.

The youngest rocks involved in the Variscan folding in North Devon are Lower Westphalian (*G<sub>1</sub>*), slightly older in the Exeter region<sup>18</sup>. Assuming that the New Red sedimentation commenced after the main folding, the date for this event can be narrowed down to somewhere between early Westphalian and late Stephanian. Early Stephanian (Asturian) is the earliest date possible for folding in the Radstock coalfield<sup>19</sup>, and is the date favoured by Fitch and Miller<sup>8</sup> for the main event, though Owen<sup>20</sup> prefers mid-Westphalian. The granite intrusion date, 295 m.y., is early Stephanian on the present time scale<sup>21</sup>; this is presumably also the date of the culminating orogenic phase and the pre-New Red volcanicity, though important orogenic movements in the Westphalian are not ruled out.

I thank Prof. P. Allen, Mr. N. E. Butcher and other colleagues at Reading for their advice.

RECENTLY, several investigators<sup>1-3</sup> have compared the <sup>87</sup>Sr/<sup>86</sup>Sr ratios of carbonate rocks from carbonatite complexes with those of sedimentary limestones. Powell *et al.*<sup>1</sup> quote a mean value of 0.7035 for carbonatites while limestones are usually greater than 0.7080. All results are normalized to <sup>87</sup>Sr/<sup>86</sup>Sr = 0.1194 and relative to a value of 0.7085 for normalized <sup>87</sup>Sr/<sup>86</sup>Sr on the Eimer and Amend standard SrCO<sub>3</sub>. Hamilton and Deans reported a mean <sup>87</sup>Sr/<sup>86</sup>Sr ratio of 0.7060 for nine carbonatites. Powell *et al.* concluded that the difference in <sup>87</sup>Sr/<sup>86</sup>Sr values demonstrates that carbonatites are not mobilized limestones. For this criterion to be effective, however, two requirements must be fulfilled: (a) there must be a negligible overlap of the strontium isotope ratios of carbonatites and limestones and (b) the <sup>87</sup>Sr/<sup>86</sup>Sr ratios of limestones must not be altered by metamorphism. Powell *et al.*<sup>1</sup> showed that a xenolith of Trenton limestone (Ordovician) from the Mount Royal gabbro (Montreal) has essentially the same <sup>87</sup>Sr/<sup>86</sup>Sr ratio as the Trenton limestone at some distance from the intrusion. From these measurements, they inferred that requirement (b) is generally satisfied. It seems to us, however, that the behaviour of a small xenolith that has merely been recrystallized but not otherwise reacted on by the enclosing magma cannot readily be extrapolated to cover the case of a large mass of limestone that might be melted and intimately incorporated in a magma with extensive reaction.

We have examined calcite separated from Grenville marble and from a number of calcite-silicate rocks that represent extensively metasomatized limestone. The specimens have been collected from well-mapped parts of the Grenville province in Ontario and Quebec and there can be no reasonable doubt that the carbonate is derived from Grenville limestone. The results obtained are shown in Table 1. Isotope ratios are normalized to <sup>87</sup>Sr/<sup>86</sup>Sr = 0.1194. The error at the 95 per cent confidence-level which has been estimated from replicate analyses of a standard solution is ±0.0006 for a single analysis and ±0.0004 for the average of two analyses. An account of the double collection system used with an A.E.I. MS 2 mass spectrometer will be given elsewhere.

While the investigation is not yet complete, there does seem to be sufficient evidence to make the following statements:

- (1) If the <sup>87</sup>Sr/<sup>86</sup>Sr ratios in the limestones described here were not affected by the metamorphism, then there must have been a very considerable spread in the <sup>87</sup>Sr/<sup>86</sup>Sr ratios in the original limestones. This range would in fact overlap to a large extent that shown by carbonatites.
- (2) If our samples are assumed to have originated with some common limestone value for the <sup>87</sup>Sr/<sup>86</sup>Sr ratio, then

Table 1

Sample description	Normalized <sup>87</sup> Sr/ <sup>86</sup> Sr
White crystalline limestone with accessory graphite and phlogopite—recrystallized Grenville marble with no introduction of components. Monmouth Twp., Ontario, Canada.	0.7071 0.7072
Calcite from calcite-phlogopite-diopside rock containing enough phlogopite and diopside to indicate considerable introduction of components from granite magmas. Monmouth Twp., Ontario, Canada.	0.7064 0.7060
Calcite from calcite-garnet-pyroxene skarn formed by metasomatism of Grenville marble by gabbro. Chandos Twp., Ontario, Canada.	0.7056
Calcite from pod of orange calcite-apatite-fluorite-pyroxene rock (calcite crystals 3" across) Grenville metasediments. North of Ottawa, Quebec, Canada.	0.7048 0.7048
Calcite from alkali feldspar-biotite-calcite rock formed at the junction of Grenville marble with a syenite intrusion. Monmouth Twp., Ontario, Canada.*	0.7038 0.7032

\* It is important to emphasize that this rock is a reaction product between Grenville marble and a syenite which does not contain any calcite. There can be no reasonable doubt geologically that the calcite in this rock was derived from Grenville marble.

there is a significant decrease in this ratio with increase in the degree of metamorphism/metasomatism. Whichever is correct it can scarcely be said that strontium isotope measurements offer a clear demonstration that carbonatites are not mobilized limestones.

We do not suggest that carbonatites are either limestone xenoliths or mobilized limestones but we doubt that the studies of strontium isotopic composition prove that they are not.

This work is supported by grants from the Canadian National Research Council and the Ontario Research Foundation to York, Farquhar and Gittins. The skarn specimen was kindly provided by Prof. D. M. Shaw of McMaster University, Hamilton, Ontario.

## GEOCHEMISTRY

### Estimation of Elapsed Time since a Certain Climatic Change for Lake Vanda

WILSON<sup>1</sup> has considered the estimation of elapsed time since a climatic change for Lake Vanda (77° 35' S., 161° 39' E.), which is 5 miles long, 1 mile wide and occupies the lowest part of the Wright Valley, an ice-free valley in Victoria Land, Antarctica.

The estimation procedure makes use of the equation:

$$C = [M/(Dt)^{\frac{1}{2}}] \exp[-h^2/(4Dt)]$$

where  $C$  is the concentration of calcium chloride at distance  $h$  from bottom after an elapsed time  $t$ ,  $h$  is the distance above bottom,  $D$  is the diffusion coefficient of calcium chloride (0.68 cm<sup>2</sup>/day at 10°—see ref. 2), and  $M$  is the total mass of calcium chloride per unit area.

Measurements were made on the concentration of calcium chloride at a distance  $h$  from bottom. Originally the data were presented by Wilson<sup>1</sup> in the form of a graph, but more recently he has presented them (personal communication) as in Table 1.

Table 1

$h$ (ft.)	$C$ (equiv./L)
0	2.36
5	2.28
10	2.12
15	1.93
25	1.53
35	0.99
45	0.473
50	0.306
55	0.142
60	0.0604
65	0.0303
70	0.0230

$h$  is the distance above bottom in feet, and  $C$  is the concentration of calcium chloride.

It should be noted that Wilson (personal communication) gives these data and points out that in Fig. 2 of ref. 1 there is an error in the concentration scale of about 0.5. This reduces the former good fit for approximately 1,200 years to the smaller value given in this communication.

It should be noted that the equation involved can be written:

$$\log C = -h^2/4Dt + \log[M/(Dt)^{\frac{1}{2}}]$$

where  $\log$  refers to natural logarithm.

For the values  $0 = h_0 < h_1 < \dots < h_n$  we have associated  $C_0, C_1, \dots, C_n$ , respectively. We write:

$$W_i = \log(C_i/C_0) = -h_i^2/4Dt \text{ for } i = 1, 2, \dots, n$$

The value of  $t^*$  which minimizes the sum of squares  $\sum_{i=1}^n (W_i - W_i^*)^2$ , where  $W_i^*$  is computed from the observed values  $C_i^*, C_1^*, \dots, C_n^*$  of  $C_0, C_1, \dots, C_n$ , is:

$$t^* = \frac{-\sum_{i=1}^n h_i^4}{4D \sum_{i=1}^n h_i^2 W_i^*}$$

If we assume that  $W_i = -h_i^2/4Dt + \epsilon_i$ , where  $\epsilon_i$  is normally distributed with mean 0 and variance  $\sigma^2$  for  $i = 1, 2, \dots, n$ , then  $1/t^*$  is normally distributed with mean  $1/t$  and variance  $16D^2\sigma^2 / \sum_{i=1}^n h_i^4$ . An unbiased estimate of  $\sigma^2$  is  $s^2$ , where:

$$(n-1)s^2 = \sum_{i=1}^n W_i^{*2} - \left( \sum_{i=1}^n h_i W_i^* \right)^2 / \sum_{i=1}^n h_i^4$$

It will follow that:

$$(1/t^* - 1/t) \left[ \left( \sum_{i=1}^n h_i^4 \right)^{\frac{1}{2}} / 4Ds \right] = T(n-1)$$

where  $T(n-1)$  is the Student  $t$ -distribution with  $n-1$  degrees of freedom. Therefore, if  $T_\alpha(n-1)$  is such that  $\text{Prob}(T(n-1) > T_\alpha(n-1)) = \alpha/2$ , then a  $(1-\alpha)100$  per cent confidence interval for  $t$  has:

$$\frac{t^* \left( \sum_{i=1}^n h_i^4 \right)^{\frac{1}{2}}}{\left( \sum_{i=1}^n h_i^4 \right)^{\frac{1}{2}} + 4Dt^*sT_\alpha(n-1)} \leq t \leq \frac{t^* \left( \sum_{i=1}^n h_i^4 \right)^{\frac{1}{2}}}{\left( \sum_{i=1}^n h_i^4 \right)^{\frac{1}{2}} - 4Dt^*sT_\alpha(n-1)}$$

when  $0 < 4Dt^*sT_\alpha(n-1) < \left( \sum_{i=1}^n h_i^4 \right)^{\frac{1}{2}}$

The method of estimation used by Wilson<sup>1</sup> was simply trial and error. He observed graphically that the observed points fell between the graph for  $t = 1,000$  and  $t = 1,500$  and that  $t = 1,200$  looked like a good fit. By the described statistical estimation method one obtains  $t^* = 984$  years and 95 per cent confidence interval  $576 \leq t \leq 3,360$ . This is a much more satisfactory method of analysis since it gives an estimate with the optimal properties of least squares as well as a measure of the accuracy of the estimate.

CHARLES DEWITT ROBERTS

National Institute of Arthritis  
and Metabolic Diseases,  
Bethesda, Maryland.

<sup>1</sup> Wilson, A. T., *Nature*, **201**, 176 (1964).

<sup>2</sup> *Handbook of Chemistry and Physics* (Chemical Rubber Publishing Co., Cleveland, Ohio, 1964).

DR. ROBERTS's treatment of my data gives additional confirmation to my tenet that the chemical gradients found in Lake Vanda can be explained by chemical diffusion and that such chemical composition profiles in Antarctic lakes can provide valuable paleoclimatic information<sup>1</sup>.

I would, however, like to make a few comments on the treatment used by Dr. Roberts. The model I used, and that adopted by Dr. Roberts, was diffusion from a planar source of negligible thickness on the bottom of a rectangular trough of infinite volume. This assumes the Lake has a flat bottom with vertical sides. As my Fig. 2 (ref. 1) and the mathematics of Dr. Roberts show, this is, in fact, a reasonable first approximation. Dr. Roberts is concerned with secondary refinements, and to do this one cannot give all

points equal loading as he has done. The data near the bottom should be loaded more highly than those further from the bottom. This is because the real Lake Vanda does not have perfectly vertical sides so that the cross-sectional area will always become larger with increasing distance from the bottom. This will lead to a lowering of the concentration faster than the rectangular model would predict—this correction, while small near the bottom, becomes more important the further one goes from the bottom. Thus the least squares fit on the basis of a rectangular trough model will always give a minimum age. In my previous communication<sup>1</sup> data were plotted to emphasize the lower region of the Lake and show that in the lower 45 ft. the experimental points lay between 1,000 and 1,500 years. It was then concluded that the true age lay between these or about 1,200 years. It can be seen in my Fig. 2 that the experimental points above 50 ft. from the bottom are better fitted by the 1,000 year age, but this was neglected for the reasons given here.

More bathometric data on Lake Vanda would enable a more accurate date to be obtained. Further corrections would also have to be made for variation of the diffusion coefficient of calcium chloride with temperatures and concentration.

These are only minor objections in that Dr. Roberts's "rectangular trough age" and my estimate are essentially in agreement. In the Antarctic there are no good dating procedures, since there are little or no carbonaceous remains and when these are found they are suspect due to the "carbon-14 age" of the original carbon, be it from glacial melt waters or from the sea.

My original paper<sup>1</sup> was to persuade geologists that Lake Vanda was not 10,000 years old, as was believed by some<sup>2</sup>, or that the presence of upper lake levels meant that it was drying up, as was believed by many<sup>3</sup>. It was also my intention to persuade them that the salt gradients in lakes could yield valuable palaeoclimatic data.

## OCEANOGRAPHY

### Observations on the Entrapment of Organic Matter within the Particle Structure of Calcareous Sediments

In the course of experiments on the metabolism of intact sediment communities we had to determine the concentration of ninhydrin-positive substances associated with the sediments. In addition, data on the uptake of free amino-acids from solution by these sediments was needed.

The organic compounds associated with natural sediments and their concentration have been well documented in recent literature<sup>1-4</sup>. Most of these analyses have dealt either with compounds in interstitial waters or in the hydrolysates of whole sediments. During the present work it became apparent that, as well as organic compounds associated with the interstitial water of these sediments, there was also a considerable amount bound within the sediment particles. The present investigation was an attempt to find the amount of this ninhydrin-positive organic matter as well as its origin.

The sediments under investigation were aerobic, calcareous sediments from Biscayne Bay, Florida. They had a uniform grain size with 90 per cent of the particles falling in the 0.5–1.0 mm range. Samples were collected by scraping the surface of shallow-water sediments to remove only the well-oxidized surface layers. These were

then freed from interstitial water and macroscopic organisms by washing and decanting repeatedly. Prolonged washing of the sediments on a coarse sintered glass filter removed as many of the microscopic organisms as possible. Sub-samples of these cleaned sediments were used immediately.

Chromatography columns were loosely packed with the sediment and wetted with artificial sea water. They were then washed with various solutions (Table 1). Some of these solutions were acidic and dissolved most of the sediment during the course of the experiment. Final complete dissolution was achieved with concentrated hydrochloric acid. The non-calcareous fraction remaining after this treatment was subjected to further washing. Samples of the solutions obtained after washing were analysed for ninhydrin-positive substances by the method of Moore and Stein<sup>5</sup> with minor modifications to eliminate the precipitate which formed in the presence of sea-water.

Table 1. ILLUSTRATION OF DIFFICULTY EXPERIENCED IN WASHING CALCAREOUS SEDIMENTS FREE OF NINHYDRIN-POSITIVE COMPOUNDS

Wash solution	Wash No.	Extinction at 570 mμ after ninhydrin colour development
Artificial sea-water, pH 8.0	1	1.050
	2	0.250
	3	0.163
	4	0.090
	5	0.068
Artificial sea-water, pH 5.5	6	0.107
	7	0.090
	8	0.152
Acetate buffer, pH 5.0	9	0.975
	10	0.650
	11	0.496
	12	0.460
	13	0.496

Distilled water	16‡	0.000

\* Sediment left overnight in twice its own volume of buffer.

† Dissolved in concentrated hydrochloric acid.

‡ Wash of siliceous sand remaining after dissolution of calcareous sand.

To reduce interference from naturally occurring organic compounds similar columns were washed with artificial sea-water until a stable low level of ninhydrin-positive substances was obtained in the wash water. The columns were then loaded with small volumes of 0.02 M amino-acid solutions. Amino-acid analyses were performed on fractions of the effluent.

Cleaned sediment samples were weighed out into clean dry flasks. A known amount of amino-acid was added in sufficient sea-water solution to exceed the water-holding capacity of the sediment. The flasks were then placed on a shaker for short periods of time to permit equilibration. The fluid was recovered by filtration on sintered glass followed by partial displacement of the liquid held by the sediment with a small volume of sea-water. Amino-acid analyses were performed on the solutions recovered from such batch uptake experiments.

Artificial sea-water was supersaturated with respect to calcium carbonate by lowering the pH to 4.0 and temperature to near freezing. Calcium carbonate was added until solid calcium carbonate persisted. The sea-water was freed of the solid material and made 0.02 M with respect to the amino-acid being tested. The pH and temperature were then raised, causing calcium carbonate to reprecipitate. The solutions were freed of the solid material and analysed for their amino-acid concentration.

Washing sediment columns with sea-water eventually yielded an eluant with a low concentration of ninhydrin-positive substances (see Table 1). However, washing with acidic solutions released ninhydrin-positive substances in proportion to the amount of sediment dissolved. These observations are interpreted to indicate the presence, on the surface of the sediment particles, of a loosely bound organic fraction. In addition there was an organic fraction within the physical structure of the particles comprising the sediments.

The column uptake experiments did not yield clear-cut results but there appeared to be some retention of the

acidic amino-acids. For example, a column of sediment ( $2.5 \times 5.0$  cm, with an estimated void volume of five ml) was washed with artificial sea-water (pH 8.0) until the effluent showed a stable low level of ninhydrin-positive substances. The column was then loaded with 10 ml. of a 0.02-M solution of aspartic acid, followed by elution with artificial sea-water. After passage of 100 ml. of the eluant through this system the effluent still possessed twice the concentration of ninhydrin-positive substances established before the addition of the amino-acid. The 45–50-ml. fraction possessed the highest concentration, indicating some retardation of the amino-acid. Similar results were not obtained with leucine or lysine.

Table 2. PERCENTAGE RECOVERY OF ADDED AMINO-ACIDS IN BATCH UPTAKE EXPERIMENTS

Amino-acid added	Percentage recovery in different experiments using the same sediment (%)
Arginine	94
Lysine	100
Serine	100
Glutamic acid	95
Aspartic acid	96
Proline	60–73
Tryptophan	78–88

Table 2 presents percentage recovery figures from the batch experiments. It would appear that the heterocyclic compounds tryptophan and proline are weakly associated with these sediments. Even they, however, could be eluted with a single wash with artificial sea-water. Artificial calcium carbonate sediments, free from organic matter, were obtained from a local water purification plant. They were sieved to conform in size with the natural sediments under study. With these sediments no uptake of free amino-acids from solution was observed nor did they show the retardation effect in column experiments.

Calcium carbonate is not usually recognized as a mineral which complexes organic matter<sup>4</sup>. This conclusion is supported by the negative results of our co-precipitation and artificial sediment experiments. It is reasonable to assume, therefore, that any uptake capacity we have demonstrated in natural sediments is due to some other factor. This is probably a surface layer of some other class of organic compounds, perhaps lipid in nature.

It is well known that varying proportions of natural calcareous sediments are biological in origin. The proportion varies from almost entirely of biological origin as in some deep-sea sediments to a relatively small biological contribution in the Bahamas Bank and analogous areas<sup>5</sup>. Calcareous plants and animals are believed to be the major source of this calcium carbonate but the possible role of micro-organisms has recently been re-emphasized<sup>6,7</sup>. The presence of organic matter within the structure of these sediments is therefore not surprising. However, the observation that in a well-oxidized surface sediment so much organic matter is preserved appears to be novel. This organic matter constitutes a net loss from the environment, as it is well protected from the usual degradation processes by being bound within the sediment particles. The only likely means by which such organic matter would leave the sediments would be by the latter's physical alteration during geological time. The entrapped organic matter thus could constitute an additional reservoir of organic matter for various geochemical processes.

In conclusion, calcareous sediments have been shown to possess weak affinities for certain nitrogen compounds of low molecular weight. This weak ability to act as adsorbents, retardants, or concentrators of organic matter is probably due to other classes of organic compounds rather than the mineral itself. However, it has been demonstrated that these sediments do possess an appreciable amount of organic matter bound with their particle structure. It appears likely that this organic matter is the residue of the organic matrix used by the plant or animal to lay down the mineral. Thus if a calcareous sediment is found to have an appreciable amount of ninhydrin-

positive substances bound within its particles the sediment may be considered to be of possible biological origin.

## CHEMISTRY

### Self-diffusion of Lead in Lead Oxide (PbO)

We have utilized lead-210 isotope and surface-counting technique to evaluate the self-diffusion coefficient of lead in lead oxide. Since lead-210 has a very weak  $\beta$ -emission (0.025 MeV) it is wellnigh impossible to estimate the activity with the conventional Geiger-Müller counters. Furthermore,  $\mu$ , the absorption coefficient, is so high that the radiations from within the bulk material do not penetrate the layers. However, we have successfully surmounted the difficulty by depositing lead-210 on one face of a pellet, allowing the daughter to build up, and following the movement of lead-210 by determining the amount of bismuth-210. We present here the relevant mathematical treatment and results.

There are three distinct possibilities when lead-210 is deposited on the pellet. They are: (1) lead-210 is in equilibrium with bismuth-210; (2) lead-210 is in excess of the equilibrium; (3) lead-210 is in deficit. In all these cases, after a length of time (30 days) the two isotopes will be in equilibrium. However, if a freshly purified lead-210 is used, only the second possibility exists.

If  $x$  be the equilibrium counting rate,  $y$  and  $z$  the amount of bismuth that is in excess or deficit at times  $t_1$  and  $t_2$ , then:

$$C_1 = x \pm y, C_2 = x \pm z$$

Where  $C_1, C_2$  are the actual counting rates at  $t_1$  and  $t_2$

Let us now review the three cases individually:

Case (i):

$$C_1 = C_2 = x = A_0$$

$$C'_1 = C'_2 = x' = A t$$

Case (ii). In this case if  $C_1 = x - y$  is the counting rate at  $t_1$  and  $C_2 = x - z$  the counting rate at time  $t_2$ , both before heating, then ( $x < y$ )  $z$  is given by  $z = y e^{-\lambda t}$ , where  $t = t_2 - t_1$  and  $\lambda = 0.693/t_{1/2}$ ,  $t_{1/2}$  being the half-life of bismuth-210:

$$C_1 = x - y \text{ (i) and } C_2 = x - y e^{-\lambda t} \text{ (ii)}$$

Multiplying equation (i) by  $e^{-\lambda t}$  and subtracting (i) from (ii) one gets:

$$C_2 - C_1 e^{-\lambda t} = x(1 - e^{-\lambda t}) \text{ (iii)}$$

Writing  $b$  for  $e^{-\lambda t}$ ,  $x$  can be expressed as:

$$\frac{(C_2 - C_1 b)}{1 - b} = x_1$$

Fig. 1

Similarly, after heating for a time  $t$ ,  $x_2$  can be given by:

$$(C'_2 - C'_1b)(1-b) = x_2$$

Case (iii). Similarly for this case where  $C_2 < C_1$  the same relation holds.

If  $C_1$  and  $C_2$  are determined at  $t_1$  and  $t_2$  before heating and  $C'_1$  and  $C'_2$  determined at  $t'_1$  and  $t'_2$  after heating for a time  $t$  then  $x_1$  and  $x_2$  correspond to  $A_1$  and  $A_2$  of equation (1) (ref. 1).

The results thus obtained are given in Fig. 1 as  $\log D$  versus  $1/T$ . The plot yields a value of 64 kcal for the activation energy. This is in remarkable agreement with that obtained by Lindner<sup>2</sup>.

### Reduction of Oxygen at the Platinum Electrode

THE formation of hydrogen peroxide is considered by some authors<sup>1-3</sup> as the possible source of the poor efficiency of oxygen electrodes in a fuel cell. Indeed, the reduction:

would proceed at a normal potential below 1.23 V if the foregoing reaction occurs in two steps:

assuming that the second step is irreversible.

The following triangular (cyclic) polarograms prove that molecular hydrogen peroxide is not produced in detectable amounts at the surface of the electrode when oxygen is reduced in acid solution at a bright platinum wire. The experiments were performed according to standard voltammetric techniques. The working electrode

was a 3.6 cm<sup>2</sup> spectroscopically pure platinum wire and the comparison a 40 cm<sup>2</sup> Hg-Hg<sub>2</sub>SO<sub>4</sub> electrode. The two electrodes were separated by three sintered glass diaphragms. The volume of the solution in the working compartment was 10 ml. The cell filled with 4 M sulphuric acid electrolyte had a resistance of 10 ohms at 27°C (ref. 4).

The significance of the shape of the triangular scanned polarogram obtained when an inert gas bubbles through the acid solution has been clearly established by Will and Knorr<sup>4</sup>. In this case, the oxidation current generated during the anodic sweep between 0.6 and 1.4 V versus the normal hydrogen electrode (NHE) is due exclusively to the building of a monolayer of platinum oxide on the bare platinum surface:

The reduction current during the following cathodic sweep is generated exclusively by the reduction of this oxide. The lack of symmetry of the polarogram as shown by the full curve of Fig. 1 is due to the irreversibility of reaction (3).

When oxygen instead of helium bubbles through the solution, the rate of reduction below 0.9 V rises above the value corresponding to the reduction of the platinum oxide layer. The increase in the reduction current, due to the reduction of oxygen, starts when approximately one-quarter of the platinum oxide layer has already been reduced to platinum. However, in the presence of oxygen the portion of the polarogram between 1.0 and 1.4 V remains identical to the shape of the polarogram obtained when helium is bubbled through the solution, as shown by Fig. 1.

On the other hand, the oxidation current between 1.0 and 1.4 V increases by approximately 6 per cent when a trace amount of hydrogen peroxide, as low as  $1 \times 10^{-4}$  mole/l., is added to the helium-bubbled solution. The same increase in current is observed when hydrogen peroxide is added to the oxygen-bubbled solution, as shown by Fig. 2. In both cases, the current is generated by the oxidation:

which proceeds together with reaction (3).

Fig. 1. Effect of the nature of bubbling gas. —, Helium; ---, oxygen; scanning rate, 5.4 V/min

Fig. 2. Effect of hydrogen peroxide with oxygen-bubbled solution. —, No  $H_2O_2$ ; ---,  $1 \times 10^{-4}$  M; ····,  $5 \times 10^{-4}$ ; - · - ·,  $10 \times 10^{-4}$  mole  $H_2O_2$ /l.

Now, the number of moles of oxygen reduced during one cycle can be calculated from the integral of the appropriate portion of the current-voltage or current-time curve of Fig. 1 since the polarization varies linearly with time. This quantity is equivalent to 13 millicoulombs per  $cm^2$  or equal to  $2.3 \times 10^{-7}$  mole for the  $3.4 \text{ cm}^2$  electrode. Therefore, the current of oxidation above 1.0 V would increase in a measurable way if only 1 per cent of this amount of oxygen was converted in  $H_2O_2$ , provided that these  $H_2O_2$  molecules remain adsorbed on the electrode during the following anodic sweep. Even if the  $H_2O_2$  molecules were instantaneously released from the electrode, the coverage would never reach 50 per cent of the surface during the cathodic sweep. Otherwise the concentration of hydrogen peroxide liberated in the 10-ml. solution of the working compartment would reach  $1 \times 10^{-4}$  mole and could be detected by the increase in oxidation current above 1.0 V.

The described experiments suggest that hydrogen peroxide is not formed as an intermediate product of the reduction of oxygen in acid solution at the platinum electrode. Hydrogen peroxide observed in other experimental conditions appears most probably as a side-product of reduction of oxygen. Consequently, hydrogen peroxide formation cannot be held responsible for the overpotential of the oxygen electrode in an acidic fuel cell.

Furthermore, the foregoing experiments confirm the hypothesis of Breiter<sup>8</sup> that the reduction of oxygen proceeds only at the contact of bare platinum atoms since the reduction proceeds during the cathodic sweep only after approximately one-quarter of the monolayer of platinum oxide has already been removed from the surface. The importance of the surface which must be cleared from the monolayer of platinum oxide before the reduction of oxygen occurs suggests, furthermore, that this catalytic reaction proceeds only after a molecule of oxygen has been adsorbed by two adjacent straight platinum atoms.

## Reaction of Pentafluoroaniline with Boron Tribromide

THE reactions between boron halides and amines have been examined extensively<sup>1-3</sup>. In theory, it is possible to substitute successively the halogen atoms in a boron halide to form the derivative  $B(RNH)_3$  from a primary amine, and the derivative  $B(R_2N)_3$  from the secondary amine. Alternative reaction schemes are possible, and in practice, if the amine is not in large excess, the final product from a primary amine is usually a borazine.

Intermediates of type II are unstable though their existence has been inferred, but those of type I have been isolated. With the secondary amines, the reaction stops at the second stage, and compounds such as  $(CH_3)_2NBBR_2$  are well known both as simple monomers and as dimers with four-membered boron-nitrogen rings<sup>4</sup>.

We find that approximately equimolar amounts of pentafluoroaniline and boron tribromide react at 25° with the evolution of hydrogen bromide and the formation of a solid mixture. At 50° the mixture melts, more hydrogen bromide is evolved, and a colourless liquid remains. This is pentafluoroanilinoboron dibromide,  $C_6F_5NHBBr_2$  (found: B, 2.9; Br, 45.2;  $C_6F_5NHBBr_2$  requires B, 3.1; Br, 45.4 per cent). The compound melts at 23° and distills unchanged at 40°–50°. It is moisture sensitive and is decomposed by water to boric acid, hydrogen bromide, and pentafluoroaniline.

At 70° pentafluoroanilinoboron dibromide decomposes quickly, with the evolution of hydrogen bromide, to a white, crystalline solid which melts at 118°–120°, and has a composition close to  $C_6F_5NBBR$  (found: B, 3.2; Br, 26.3; calc. for  $C_6F_5NBBR$ : B, 3.9; Br, 29.4 per cent). The infra-red spectrum of this material shows a weak absorption at  $3,425 \text{ cm}^{-1}$  in the position of the strong N—H frequency of the dibromide, which suggests that this is the contaminant. There is also a strong absorption, nearly absent in the dibromide, at  $1,380 \text{ cm}^{-1}$ , which lies in the region ( $1,300$ – $1,490 \text{ cm}^{-1}$ ) expected for boron-nitrogen ring vibrations in borazines<sup>5</sup>. So far, it has not proved possible to remove the contaminant from the material, which is almost certainly *tris-N*-pentafluorophenyltribromoborazine.

In benzene, pentafluoroaniline reacts with boron tribromide at 10° to give a crystalline adduct which appears to be the addition complex  $Br_2B - \overset{+}{N}H_2(C_6F_5)$ .

Pentafluoroanilinoboron dibromide is the first example of a type II intermediate to be actually isolated from the reaction between a primary amine and a boron halide. Its reactivity and physical appearance suggest that it is monomeric, as the dimeric dihalides are air-stable solids. On standing, specimens appear to form the borazine slowly even at room temperature, so it is unlikely that the dimer will ever be isolated in a pure state.

### Free Radical Formation in the Neutral Sulphitation of Wood at High Temperature

In a previous report<sup>1</sup>, it was shown that, when wood and cellulose, pretreated with sodium hydroxide and afterwards freeze-dried, were rapidly heated in the cavity of an electron spin resonance (ESR) spectrometer to a temperature between 180° and 190° C, rapid formation of free radicals (radical centres) was recorded, and it was found that within a relatively short time free-radical decay took place, following approximately an exponential function. After cooling, a limited number of free radicals remained in the specimens; these free radicals were quite stable over a considerable period of time and were considered to be trapped by a 'cage effect' of the polymers.

A question of interest was whether similar phenomena take place when wood, holocellulose and cellulose are treated in the same way but impregnated with water-free Na<sub>2</sub>SO<sub>3</sub> instead of NaOH. Such knowledge might contribute towards a better understanding of high-temperature neutral-sulphite pulping of wood.

The following materials were used: (a) black spruce sawdust (the fraction which passed the 40-mesh sieve but was retained by the 60-mesh sieve); (b) chlorite holocellulose prepared from the same black spruce sawdust by a series of mild chloriting stages similar to the procedure of Wise *et al.*<sup>2</sup>; (c) commercial, acetate grade, high alpha-cellulose (98 per cent) pulp.

These materials were subjected to 30 min impregnation at 83° C in a 10 per cent Na<sub>2</sub>SO<sub>3</sub> solution (pH about 8.6) in a ratio of 1 : 20. At the end of the impregnation period, the materials were separated from the liquor on a sintered glass crucible and then pressed to remove the remaining liquor excess. Later, they were freeze-dried to remove water; finally, they contained about 25 per cent Na<sub>2</sub>SO<sub>3</sub>. Weighed specimens were introduced into quartz capillaries; after evacuation and filling the capillaries with nitrogen at atmospheric pressure, the capillaries were sealed.

The filled capillaries were rapidly heated to 190° C in the cavity of a Varian Associates model 'V-4500' electron spin resonance spectrometer by a stream of hot nitrogen. Single line signals (first derivatives) were found and recorded (modulation 630, gain 630, range 16) with increasing time of heating. For comparison, the changes of the signal area (sq. cm) of the three specimens, calculated free of inorganics, and based on the same initial wood weight are presented in Fig. 1. The holocellulose yield

was about 71 per cent and that of the high-alpha-cellulose pulp about 40 per cent. Thus, the curves show how holocellulose and the high alpha-cellulose pulp obtained in these ratios from the same wood weight compare with the initial wood.

It can be seen that free radicals were formed with each material investigated, and that the concentration of the radicals trapped in the polymeric substances increased with increase of the heating time. However, after a definite reaction time (wood, about 25 min; holocellulose, about 20 min; high alpha-cellulose pulp, about 15 min) a levelling-off was observed. Probably, as polymer degradation progressed, the 'cage effect' of the degraded material approached a distinct limit value. In contrast to the alkaline pulping experiments<sup>1</sup>, no immediate formation of free radicals in very high concentrations at the very start of reaction, followed by free-radical decay according to an approximate first-order pattern, was observed. This seems to indicate that the mechanisms of alkaline delignification and high-temperature sulphitation of the wood are distinct phenomena.

As shown in Fig. 1, for equal reaction times, the ESR signal area as a measure of the free radical concentration decreased in the order: wood, holocellulose, high alpha-cellulose pulp. Remarkably, the holocellulose values were relatively high when compared with those of the wood; even if correction was made for the alpha-cellulose portions of the holocellulose, these values still accounted for about half those of the wood. This appears to constitute evidence that during reaction, besides thermal degradation and sulphonation of the lignin, considerable changes of the hemicellulose portions also took place, both resulting in free radical formation.

This work was carried out partly at the Pulp and Paper Research Institute of Canada, Montreal, and partly at the National Research Council, Ottawa, and I thank these organizations for their help, and Dr. J. R. Morton for his co-operation in recording the ESR spectra.

### Synthesis of *Tris*-(hexafluoroacetylacetonato)-Chromium (III)

REDUCTION of Cr(VI) in the presence of chelating ligands offers a promising approach to synthesis of Cr(III) chelates in high yield. This principle was used by Aikens and Reilly<sup>1</sup> to devise a rapid chelometric method for determination of chromate. Reduction of chromate with bisulphite in a buffered solution of ethylenediaminetetraacetic acid (EDTA) gave quantitative formation of Cr(III)-EDTA. The quantitative yield of Cr(III) EDTA suggested that this might be the basis of a general method for synthesis of Cr(III) complexes. We have now applied this principle to synthesis of Cr(III) chelates of much lower stability as exemplified by *tris*-(hexafluoroacetylacetonato)-Cr(III).

Efforts to synthesize *tris*-(hexafluoroacetylacetonato)-Cr(III) in aqueous solution in a manner similar to the synthesis of Cr(III) EDTA were unsuccessful. Attempted synthesis in hydroxylic non-aqueous solvents, such as methanol with paraldehyde as the reductant, also failed. A successful synthesis was based on the heterogeneous reaction of hexafluoroacetylacetone with potassium dichromate. This reaction is interesting because evidently the ligand acts as the reductant.

0.5 g (0.0017 mole) of finely powdered potassium dichromate was placed in a 100-ml. round-bottom flask and covered with 4.16 g (0.020 mole) of the ligand. The flask was fitted with a water-cooled condenser and the

Fig. 1. Signal areas in relation to reaction time. A, Wood (0.015 g); B, holocellulose (0.0105 g); C, high-alpha-cellulose pulp (0.006 g).

solution was refluxed gently for 3 h, during which time the liquid changed from colourless to dark green. Fifty ml. carbon tetrachloride was added and refluxing continued for 30 min. The solution was filtered and the filtrate was evaporated to dryness by a stream of dry air. The yield of *tris*-(hexafluoroacetylacetonato) Cr(III) was 1.85 g (80 per cent based on potassium dichromate). Calculated for  $\text{Cr}(\text{C}_6\text{HF}_5\text{O}_4)_3$ : C, 26.76 per cent; H, 0.45 per cent; F, 50.80 per cent. Found: C, 27.04 per cent; H, 0.68 per cent; F, 51.30 per cent. The infra-red spectrum and melting point ( $84^\circ$ ) of the compound were determined and agree well with the data of Morris *et al.*<sup>2</sup>

## BIOCHEMISTRY

### Decomposition and Carcinogenic Activity of Azoxyglycosides

THE toxicity of leaves and seeds of cycads to animals and humans is well established (for review, see ref. 1). The toxic constituents are azoxyglycosides of which the simplest are cycasin (I;  $R = \beta$ -D-glucopyranosyl)<sup>2</sup> and macrozamin (I;  $R = \beta$ -primeverosyl)<sup>3,4</sup>. More recently, liver damage<sup>5</sup> and carcinogenesis<sup>6</sup> have been observed to follow ingestion of the seeds or extracts containing the unstable aglycone, methylazoxymethanol (I;  $R = \text{H}$ ) (ref. 5). The latter may theoretically decompose to the alkylating agent, diazomethane, a potent carcinogen<sup>7</sup>, and is indeed isomeric with hydroxydimethylnitrosamine through which dimethylnitrosamine may be transformed *in vivo* to the same active carcinogen<sup>8</sup>.

That cycasin and macrozamin may be effective methylating agents *in vitro* has now been demonstrated by the production of anisole (40–50 per cent yield, based on azoxyglycoside) when a solution of the glycoside in molten phenol is treated with a drop of concentrated sulphuric acid and warmed until evolution of gas ceases (2–3 min). No reaction occurs in the absence of strong acid, nor is any trace of anisole produced when azoxyglycoside is hydrolysed in hot dilute sulphuric acid containing a large excess of phenol. This behaviour is analogous to that of benzaldazine monoxide<sup>9</sup>, and formaldehyde monoxide (II) may be an intermediate, formed by loss of water from initially produced aglycone.

Azoxyglycosides are rapidly degraded by alkali to a variety of products including cyanide ion, ammonia, methylamine, nitrogen and formic acid; the sugar component is liberated even with cold dilute ammonia<sup>10</sup>. The first step is now formulated as (a) in the annexed scheme (Fig. 1). A little anisole (c. 2 per cent) is produced when cycasin is degraded by aqueous alkali buffered to pH 10 by an excess of phenol, so that the postulated intermediate, formaldehyde monoxide (II), may break down partly to formaldehyde and free diazomethane in alkali. Most of these products, however, are apparently diverted into

acetaldehyde, their product of (perhaps intramolecular) reaction (b), as shown by the appearance of iodoform (20 per cent yield) on treatment of cycasin or macrozamin with aqueous alkaline hypiodite. The presence of acetaldehyde has not been demonstrated directly but the same yield of iodoform was obtained from an equimolar mixture of *N*-nitrosomethylurea and formaldehyde on treatment with alkali followed by hypiodite, none being obtained by similar treatment of these compounds alone. The iodoform probably does not arise from direct iodination and cleavage of the 'active' methyl group (but see ref. 10) in the aglycone, for the electronically similar nitromethane yields no iodoform under the same conditions.

Fig. 1

The formation of cyanide ion in alkali is now postulated to follow an alternative mode (c) of decomposition of formaldehyde monoxide (II), which finds a close analogy in the base-induced cleavage of aldehyde quaternary hydrazones to nitriles and tertiary amines<sup>11</sup>. The other product expected in the present case, formaldoxime (III), has not been isolated but evidence for its presence is found in (i) the production of formic acid (45 per cent), the hydrolysis product of formaldoxime in dilute acid<sup>12</sup>, when the alkaline solution is acidified with dilute sulphuric acid and distilled<sup>3</sup>, and (ii) the slow deposition of formaldehyde-dimedone (26 per cent) when the alkaline solution is buffered to pH 4 with acetic acid and sodium acetate in the presence of dimedone. The small amounts of methylamine and ammonia produced from macrozamin in boiling alkali<sup>3</sup> may also arise from decomposition of formaldoxime.

### Mechanism of Choline Sulphate Utilization In Fungi

CHOLINE sulphate is synthesized by higher fungi<sup>1</sup>, algae<sup>2</sup> and plants<sup>3</sup>. In fungi it is found in high concentration in the mycelium<sup>4</sup> and in spores<sup>5</sup> and is thought to act as a store of sulphur<sup>6,7</sup> and possibly carbon and nitrogen. Synthesis of choline sulphate<sup>8,9</sup> involves activation of inorganic sulphate by the enzymes ATP-sulphate adenylyltransferase (*EC* 2.7.7.4), (ATP-sulphurylase) and ATP-adenylyl 3'-phosphotransferase (*EC* 2.7.1.25), (APS-kinase), to give adenosine 3'-phosphate 5'-sulphatophosphate (PAPS) and the subsequent transfer of the

sulphate group of PAPS to choline catalysed by 3'-phosphoadenylylsulphate: choline sulphotransferase (EC 2.8.2) (choline sulphotransferase)<sup>8</sup>. The mechanism of the utilization of the sulphur of choline sulphate for cysteine synthesis has been in some doubt. A reversal of the choline sulphotransferase reaction to give PAPS which could then be converted to  $\text{SO}_4^{2-}$  and then to cysteine has been ruled out<sup>9,10</sup>. Several workers have failed to detect a choline sulphatase in fungi<sup>11,12</sup>, and while this enzyme has been detected in *A. sydowii* and *P. chrysogenum*<sup>13</sup>, the activity of the enzyme was very low and its physiological significance uncertain. Evidence is now presented confirming the presence of choline sulphatase in fungi and establishing that this enzyme is obligatory for choline sulphate utilization.

A number of parathiotropic mutants<sup>14</sup> of *Aspergillus nidulans*, A.69, and mutants A and C of a biotin-less mutant of *Aspergillus nidulans* were examined. Growth requirements were ascertained on Czapek-Dox liquid medium in which sulphate-containing salts were replaced by the corresponding chlorides. Choline sulphate synthesis *in vivo* and *in vitro*, overall PAPS synthesis and choline sulphotransferase were determined by methods used previously<sup>8</sup>, and ATP-sulphurylase was determined by the molybdolysis technique<sup>15</sup>. APS-kinase was assayed by following the conversion of adenosine 5'-[<sup>32</sup>S]-sulphatophosphate (APS) to PAP<sup>32</sup>S and choline [<sup>32</sup>S]-sulphate in the presence of ATP, choline and choline sulphotransferase. Sulphate and choline sulphate transport through the mycelial wall was measured by suspending mycelia for 15 min at room temperature in media containing <sup>35</sup>SO<sub>4</sub><sup>2-</sup> or choline [<sup>32</sup>S]-sulphate, filtering and assaying the loss of radioactivity from the media. Choline sulphatase in mycelia was measured by a method similar to that used by Segal<sup>13</sup>.

Heterokaryosis tests confirmed Hockenbush's findings<sup>14</sup> that the mutants could be divided into four main groups:

I, gamma; II, iota; III, eta; IV, alpha, beta, zeta. A and C formed heterokaryons with all other mutants and thus constitute a fifth group. A scheme has been drawn up (above), based on the positions of the enzyme blocks as elucidated by *in vitro* assay (Table 1), which explains the growth requirements of the fungi and their ability to synthesize choline sulphate *in vivo*. The scheme envisages the obligatory hydrolysis of choline sulphate to inorganic sulphate and choline before its sulphur can be utilized for cysteine synthesis.

The two key mutants are iota and A. The former cannot grow on sulphate or choline sulphate, while A can grow on choline sulphate but not on sulphate. Mutant gamma lacks the enzyme ATP-sulphurylase and thus cannot utilize inorganic sulphate supplied as such or arising from the hydrolysis of exogenous choline sulphate although it will transport both sulphur sources into the mycelia. Mutant A does not grow on inorganic sulphate since it cannot transport sulphate into the mycelia. When grown on cysteine as a sulphur source it does not synthesize choline [<sup>32</sup>S]-sulphate from exogenous <sup>35</sup>SO<sub>4</sub><sup>2-</sup> but it does possess all the enzymes for choline sulphate synthesis. There is no block to the utilization of choline sulphate by this mutant since the enzymes are present for choline sulphate transport, hydrolysis and sulphate utilization.

The findings of others that choline sulphatase is absent<sup>11,12</sup> or present only in trace amounts<sup>13</sup> in mycelia are explained by the fact that the enzyme is repressed under conditions of sulphur sufficiency and it is only as all other sulphur reserves are being used up that enzyme is de-repressed and choline sulphate utilized. The *in vivo* operation of choline sulphatase and the absence of any alternative form of choline sulphate utilization were demonstrated in short-term experiments in which mycelia which have been starved of sulphur were incubated in media containing choline [<sup>32</sup>S]-sulphate. In A.69, <sup>35</sup>SO<sub>4</sub><sup>2-</sup>, [<sup>32</sup>S]-cysteine and other labelled sulphur compounds were

Table 1. GROWTH REQUIREMENTS AND ENZYME PATTERNS OF *A. nidulans* MUTANTS

Fungus	SO <sub>4</sub> <sup>2-</sup>	Growth on			Choline sulphate synthesis		ATP-sulphurylase	APS kinase	Choline sulphotransferase	Choline sulphatase	SO <sub>4</sub> <sup>2-</sup> transport	CS transport
		CS	SO <sub>4</sub> <sup>2-</sup>	Cysteine	<i>in vivo</i>	<i>in vitro</i>						
Wild-type A69	+	+	+	+	+	+	+	+	+	+	+	+
Gamma	+	+	+	+	+	+	+	+	+	+	+	+
Iota	-	-	+	+	-	-	+	+	+	+	+	+
Eta	-	-	+	+	+	+	+	+	+	+	+	+
Alpha, beta, zeta	-	-	+	+	+	+	+	+	+	+	+	+
A, C	-	+	+	+	-	+	+	+	+	+	-	+

produced in the mycelia, but in mutant gamma, which lacks ATP-sulphurylase, the only radioactive compound produced was  $^{35}\text{SO}_4^{2-}$ . A further point requiring clarification was whether the *in vivo* release of sulphate from choline sulphate was the result of the direct action of a sulphatase or only followed after the catabolism of the carbon skeleton. That a choline sulphatase was operative *in vivo* was implied by the demonstration that choline sulphate could act as a source of sulphur and of choline for two cholineless mutants (ATCO 14078 and 14714) of *Neurospora crassa*<sup>16,17</sup>.

### Acid Nucleases of the Bovine Adrenal Medulla

THE chromaffin granules of the adrenal medulla are characteristic cell organelles which serve the function of amine storage. Earlier work has shown that these granules are distinct from mitochondria<sup>1</sup>.

A relationship between lysosomes and secretory granules has been discussed<sup>2</sup>, particularly where the secretion product of the granules is an enzyme. However, a relation between the chromaffin granules and lysosomes may also have to be considered<sup>3</sup>. It is known that the chromaffin granules, like the lysosomes, release their contents into hypotonic media.

A possible connexion between lysosomes and chromaffin granules is of particular interest in view of a recent report on the occurrence of a ribonuclease (RNase) in the chromaffin granule fraction<sup>4</sup>.

During a recent investigation of the soluble protein obtained from a lysate of chromaffin granules it was noted that the RNase was present in the soluble lysate and that the latter also contained a deoxyribonuclease (DNase), and we have examined some of the properties of these enzymes.

Yeast RNA and calf thymus DNA were used as substrates. After an incubation for 1 h at 37° C the RNA or DNA was precipitated and the acid-soluble nucleotides determined by measuring the absorption at 260 mμ; this was supplemented, for confirmation, by total phosphate analysis.

Purified fractions of chromaffin granules were lysed in *tris*-sodium succinate buffer of pH 5.9 and of low ionic strength ( $I \approx 0.015$ ), as recently described<sup>5</sup>. After lysis, more than 80 per cent of both RNase and DNase activities were recovered in the supernatant fluid on centrifugation. The soluble lysate was fractionated in the same buffer on a column of 'Sephader G-200'. The enzymes could be

separated from 50 per cent of the total soluble protein. The enzymic activities emerged in two overlapping peaks; the distribution coefficient,  $K_d$  (ref. 6), was 0.201 for RNase and 0.178 for DNase. The enzymatic activities for the peak fractions were determined and expressed in terms of μM of acid-soluble P/mg protein/h; these values were 2.74 for RNase and 2.72 for DNase. In the experiments to be described below, pooled fractions from each peak were used.

The RNase of the soluble lysate from bovine adrenal medulla differed from the RNase of bovine pancreas in that it acted on RNA 'core', and in its thermostability and in its pH optimum; the latter was 5.5 for the adrenal enzyme, as compared with 7.3 for the pancreas enzyme<sup>7</sup>. The pancreas enzyme is known to be very stable to heat. On the other hand, the rat liver lysosomal enzyme has a pH optimum similar to that of the adrenal enzyme and is thermostable<sup>8</sup>; it also acts on RNA 'core'<sup>9</sup>.

The optimal pH for the adrenal medullary DNase, in sodium acetate buffer of  $I = 0.136$ , was 4.6. This enzyme was not inhibited by  $\text{Cu}^{2+}$  concentrations up to  $2 \times 10^{-4}$  M, whereas the RNase of the adrenal lysate showed a 50 per cent inhibition with  $2.5 \times 10^{-4}$  M  $\text{Cu}^{2+}$ .

The observations show that the RNase described by Philippu and Schümann<sup>4</sup> is present in the soluble protein fraction and also that an acid DNase is present in the same lysate. The material used in this study was obtained from the bovine adrenal medullary 'large granule' fraction by ultracentrifugation over a sucrose density gradient. Although a possible contamination of the chromaffin granules by either mitochondria or microsomes can be excluded as a source of the enzymatic activities studied, the possibility remains that the two enzymes are lysosomal in origin. Two alternative interpretations offer themselves: either the presence of the two acid hydrolases is an expression of a close relationship between chromaffin granules and lysosomes, or the two enzymes are located not in the chromaffin granules but in lysosomes which might be present in the particulate fraction isolated from the chromaffin tissue.

### Enzymatic Synthesis of the Sugar Esters of Hydroxy-aromatic Acids

GLUCOSE esters (1-O-acyl derivatives) of hydroxycinnamic acids have recently been shown to be widely distributed among higher plants<sup>1</sup>. They are also the most common derivatives produced when the free acids are fed to a wide variety of plants even in cases where the species examined contained either a different derivative of the acid in question or no trace of it at all<sup>2</sup>. In spite of this, however, comparatively little is known of the way in

which these glucose esters are synthesized. Although 1-*O*-anthraniloyl glucose has been shown to be formed from anthranilic acid and uridine diphosphoglucose (UDPG) in the presence of an enzyme preparation from *Lens esculentum*<sup>1</sup> it has been suggested that esters of phenolic acids are more probably synthesized from free glucose and the acyl coenzyme A derivative<sup>2</sup>. This hypothesis was presumably put forward because it has already been shown that many phenols form *O*-glucosides with UDPG in the presence of suitable enzyme systems<sup>3</sup>.

We report here that the glucose esters of the four commonly occurring hydroxycinnamic acids (*p*-coumaric, caffeic, ferulic and sinapic acids) are readily formed in good yield when the acids are incubated with a two-mole excess of UDPG and an acetone powder prepared from leaves of geranium (*Geranium zonale* cv. 'Paul Crampel') at pH 8.4 and 37°. Slightly smaller amounts were formed at pH 9.4 and 10.4, but no esters could be detected at pH 5.7 or 7.4. At pH 7.4, glucose esters were also formed from simple phenols (for example, *p*-cresol) incubated with UDPG in the presence of the same enzyme preparation from several plants<sup>4</sup>. No

higher breaking strength, whereas a compact matrix shows a lesser breaking strength. Up to now, attempts to correlate the varying degrees of egg-shell calcification with the mucopolysaccharide content have been unsuccessful. These attempts were carried out on egg-shells that had been decalcified with EDTA<sup>5,6</sup>.

We have now conducted experiments on non-decalcified egg-shells and investigated the correlation between the mucopolysaccharide content of the shells and their breaking strength. Fifteen hundred eggs were arranged in thirteen groups according to the breaking strengths and the mucopolysaccharide content of collective samples determined. Mucopolysaccharide was determined as uronic acid, and total organic material was determined as total nitrogen. The breaking strengths of the egg-shells was determined according to Rauch<sup>7</sup>, the uronic acid according to Dische<sup>8</sup> and nitrogen according to Kjeldahl.

Fig. 1. The vertical bars indicate the mean ( $\pm$  S.E.) differences in lipase activity between untreated controls (27 samples) and homogenates treated with 0.01 (15), ( $P < 0.001$ ), 0.1 (15), ( $P < 0.001$ ) and 10.0 (16), ( $P < 0.001$ )  $\mu$ units of ACTH per flask. The ordinate is the increase in lipase activity attributable to ACTH. Mean lipase activity by the untreated controls (27) was  $1.46 \pm 0.05$   $\mu$ equiv. FFA (10 mg) 2 h.

in  $\mu$ -equiv. of free fatty acids released into the incubation medium during the time of incubation per 10 mg of fresh weight adrenal tissue.

As seen in Fig. 1, all doses of ACTH which were used in our experiments markedly activated the rate of adrenal lipase, and this stimulation was related to the doses of ACTH. These findings correlate well with many histological results which demonstrated the fall of adrenal lipids after administration of ACTH or stress<sup>4-6</sup> and confirmed the histochemical findings of activated adrenal lipase after administration of ACTH *in vivo*<sup>7</sup>.

It is not yet possible to explain the significance of these findings in relation to the mode of action of ACTH on adrenal steroidogenesis, but several possibilities may be suggested. The neutral fats are depleted by ACTH-activated adrenal lipase and the fatty acids are released. These fatty acids could: (a) be converted to acetoacetyl co-enzyme A and acyl co-enzyme A, which are considered as precursors of adrenal steroids; (b) be oxidized to CO<sub>2</sub> and NAD; NADP reduced during this oxidation could be used in hydroxylating reactions of adrenal steroidogenesis.

In conclusion, ACTH has a definite direct dose-dependent action on the activity of adrenal lipase in the rat adrenal; the relation of this action to adrenal function is not yet clear.

### Arborization Patterns in Human Bile

FERN-LIKE or coralline arborization patterns have been observed in human bile allowed to desiccate and examined microscopically. Blumenkrantz and Kohan<sup>1</sup> call this phenomenon 'rhythmic crystallization', and suggest a relationship between paucity of arborization patterns and the presence of biliary lithiasis. Their work was carried out on bile obtained by duodenal intubation.

The occurrence of the arborization phenomenon in body fluids is thought to be due to an interaction of macro-

molecules of the mucin type together with electrolytes. The mechanism of formation of these patterns is postulated to be a retardation of the normal crystallization process of sodium chloride when macromolecules are present. In the absence of macromolecules, arborescent and dendritic phases of crystallization are transitory stages in the formation of typical salt crystals according to Blumenkrantz and Moreno<sup>2</sup>.

The arborization phenomenon is of clinical value in the study of mucus from the female genital tract. Arborization is quite marked during periods of oestrogenic activity, and has been shown to be the result of relatively high concentrations of NaCl in cervical mucus<sup>3</sup>.

In this study, human bile from individuals with and without gallstones was obtained by direct puncture of the gallbladder at surgery. Where possible, hepatic bile was obtained from the common duct simultaneously. Hepatic bile was also studied in post-operative patients with 'T' tubes. A drop of bile was placed on a glass slide, allowed to desiccate at 37° C and when, desiccation was complete, studied microscopically.

It was found that hepatic bile always produced the arborization patterns seen in Figs. 1a and 1b. The fern-like pattern tended to occur at the edges of the drop, while

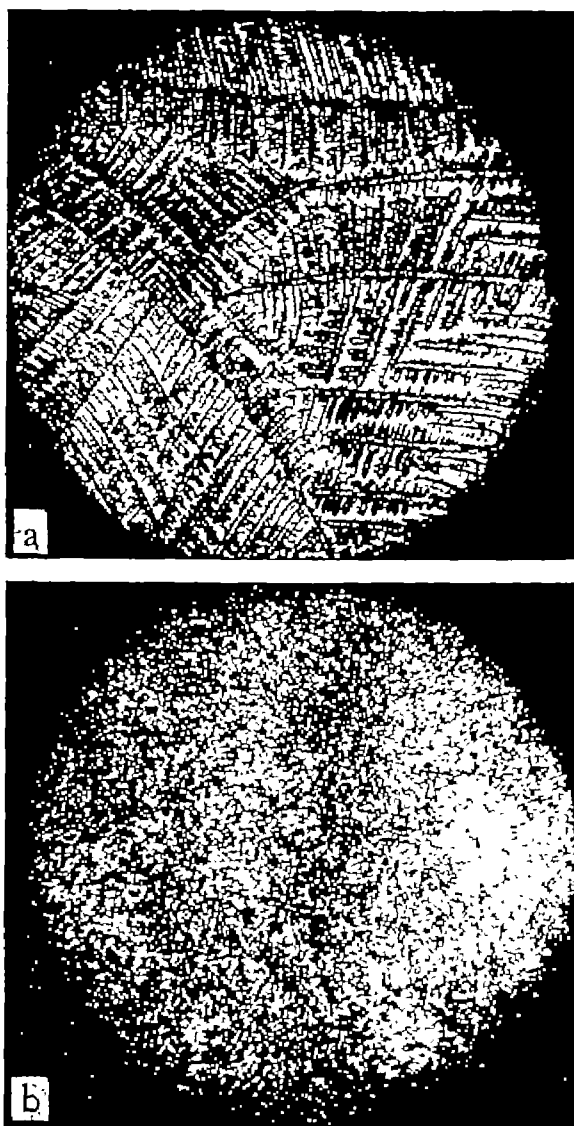

Fig. 1. (a) Fern-like pattern seen in desiccated hepatic bile ( $\times 48$ ); (b) coralline pattern seen in desiccated hepatic bile ( $\times 48$ ).

Fig. 2. Fern-like pattern produced in dialysed (electrolyte free) hepatic bile by the addition of NaCl ( $\times 48$ )

Fig. 3. Fern-like pattern reproduced in gallbladder bile by addition of excess NaCl ( $\times 48$ )

the coralline patterns occurred nearer the centre. On occasion the coralline patterns were absent, and fern patterns predominated. Dialysis of hepatic bile against distilled water caused the arborization patterns to disappear when the bile was desiccated. Addition of NaCl to dialysed hepatic bile caused the patterns to reappear, as seen in Fig. 2. Redialysis against isotonic saline gave the same result. The addition of KCl to dialysed hepatic bile caused a similar but not identical pattern to appear. The addition of  $\text{NaHCO}_3$ ,  $\text{MgCl}_2$  or  $\text{MgSO}_4$  to dialysed hepatic bile did not cause the appearance of arborization patterns. Since the gallbladder concentrates bile, hepatic bile was evaporated *in vacuo* so that it was concentrated up to ten times. The arborization patterns were unchanged.

Gallbladder bile gave little or no arborization pattern. A pattern similar to that in hepatic bile was seen in only one of 22 gallbladder bile specimens examined. This occurred in bile from a gallstone-containing gallbladder. Sparse arborization patterns were seen in two of nine normal gallbladder bile specimens, and in five of 13 gallbladders containing gallstones.

Gallbladder bile, in which the arborization pattern was absent, and hepatic bile, in which the pattern was quite striking, were obtained simultaneously from a patient undergoing operation for cholelithiasis. The addition of NaCl to the gallbladder bile produced the arborization pattern seen in Fig. 3. Dilution of the original gallbladder bile up to ten times with distilled water did not cause the arborization patterns to appear.

These specimens of bile were analysed for sodium, chlorine and potassium in an Autotechnicon 'Auto-Analyzer'. The results obtained agreed well with reported values except that chloride in gallbladder bile was somewhat higher than the values reported, though it was lower than in hepatic bile. The data are summarized in Table 1.

Table 1. ELECTROLYTE CONTENT OF GALLBLADDER AND HEPATIC BILE (Ranges from refs. 4, 5 in parentheses)

	Na m.equiv./l.	Cl m.equiv./l.	K m.equiv./l.
Gallbladder (arborization absent)	201.5 (122-275)	61.8 (15-30)	12.8 (4.7-12.5)
Hepatic (arborization marked)	145 (131-164)	105 (75-110)	6.3 (2.6-17.0)

These results demonstrate a physicochemical difference between gallbladder and hepatic bile. There is an inhibition of the arborization patterns on desiccation of gallbladder bile which is not related to simple passive concentration of hepatic bile. A possible explanation of this inhibition of arborization is that electrolytes may be bound in ionic aggregates or micelles during the process of concentration of bile in the gallbladder. We found no correlation between the arborization phenomenon in human bile and the presence or absence of biliary lithiasis when specimens were obtained directly from the gallbladder or common bile duct.

### Changes of Histone Composition in the Developing Chick Embryo

THE possible role of histones as gene suppressors has been discussed by many authors<sup>1-3</sup>. If histones do have such a function, one might expect to find some qualitative or quantitative changes in the histone pattern during the course of development, reflecting steps in the processes of differentiation. However, up to now no conclusive evidence of this has been produced. Small changes have been demonstrated in the electrophoretic pattern of total nuclear histone from embryonic chick liver during development<sup>4</sup>.

The following results were obtained from chick embryos from an age of 2 days after incubation and onwards. A quantitative recovery and subsequent fractionation of the total amount of histone, nuclear as well as cytoplasmic, has been attempted.

Organs or whole embryos were homogenized in cold 0.14 M NaCl-0.01 M Na-citrate. The precipitated nucleoprotein was washed at least twice with the saline citrate and the histones were extracted with 0.25 N HCl. The yield was 93-95 per cent of the histone amount directly obtained from acid extraction of acetone-dried material. Acid contaminants, such as polysaccharides, had to be removed, to avoid interference with subsequent fraction-

ation on carboxymethyl cellulose (CMC) (ref. 7). These acid compounds were firmly attached on 'Dowex 1' during afterwashing with 0.1 N HCl, while the histones were quantitatively recovered. Hydrogen ions were removed by filtering on 'Sephadex G 25' with acetate buffer (pH 4, ionic strength 0.02). The recovery of histone after gel-filtration was more than 95 per cent and is higher than after dialysis. The fractionation of the histones was made on CMC (ref. 8). The total recovery was about 90 per cent. Only protein from the  $F_1$  complex soluble in 5 per cent TCA was regarded as highly lysine rich histone. To obtain a stable ratio  $F_1/F_2$ , the CMC-columns were always loaded with the same quantity of histone per weight of ion exchange mass. The three fractions were also characterized by the use of the Sakaguchi reaction. The arginine ratio was in conformity to that of the corresponding fractions from thymus histone. Histones from the early embryos (represented in Fig. 1) were run on micro-columns. All preparations except the fractionations were made at 0–3° C.

The ratio of histones to DNA (w/w) does not vary during embryogenesis. This ratio was  $1.24 \pm 0.019$  in whole embryos during the 4th–16th day of development. In another series of whole embryos, 2–5 days old, the ratio was  $1.10 \pm 0.050$  and without any trend. The somewhat lower value from these young embryos may depend upon the micro-method used for this material. In embryonic livers during the developmental period of 10–20 days, the histone DNA ratio was  $1.21 \pm 0.028$ , also without any tendency to change.

However, if the total histone is separated into the three fractions, lysine rich ( $F_1$ ), slightly lysine rich ( $F_2$ ) and arginine rich ( $F_3$ ), there can be seen a tendency for this histone pattern to change during the early embryonic period (2–5 days). There occurs a gradual transformation of an embryonic pattern in which the amounts of the three fractions are similar to an adult pattern where the amount of  $F_1$  is high and that of  $F_2$  is low. The same trend appears in both experimental series (Fig. 1). The cytoplasm of the early embryonic cells encloses yolk granules. The yolk contains basic protein with a relatively high amount of  $F_1$ . The ratio  $F_1 : F_2 : F_3$  is 47 : 34 : 19. However, we have found that this incorporated protein amounts to less than 10 per cent of the total histone measured in the cell, and therefore the observed change in pattern can only to a small extent be due to a gradual decomposition of cytoplasmic yolk granules.

Furthermore, the change from an embryonic to an adult histone pattern can also be observed as a trend in single organs, erythrocytes and liver, during a later embryonic period, 10–16 days (Fig. 2). In other organs (eyes, heart, brain) such a trend is absent or insignificant and

Fig. 1. The relative amount of the three histone fractions during the early development of the chick embryo. The change tendency for each fraction is marked by arrows. White circles,  $F_1$  (lysine-rich histone); cross circles,  $F_2$  (slightly lysine-rich histone); black circles,  $F_3$  (arginine-rich histone). Each point in the diagrams represents values from about 50 whole embryos

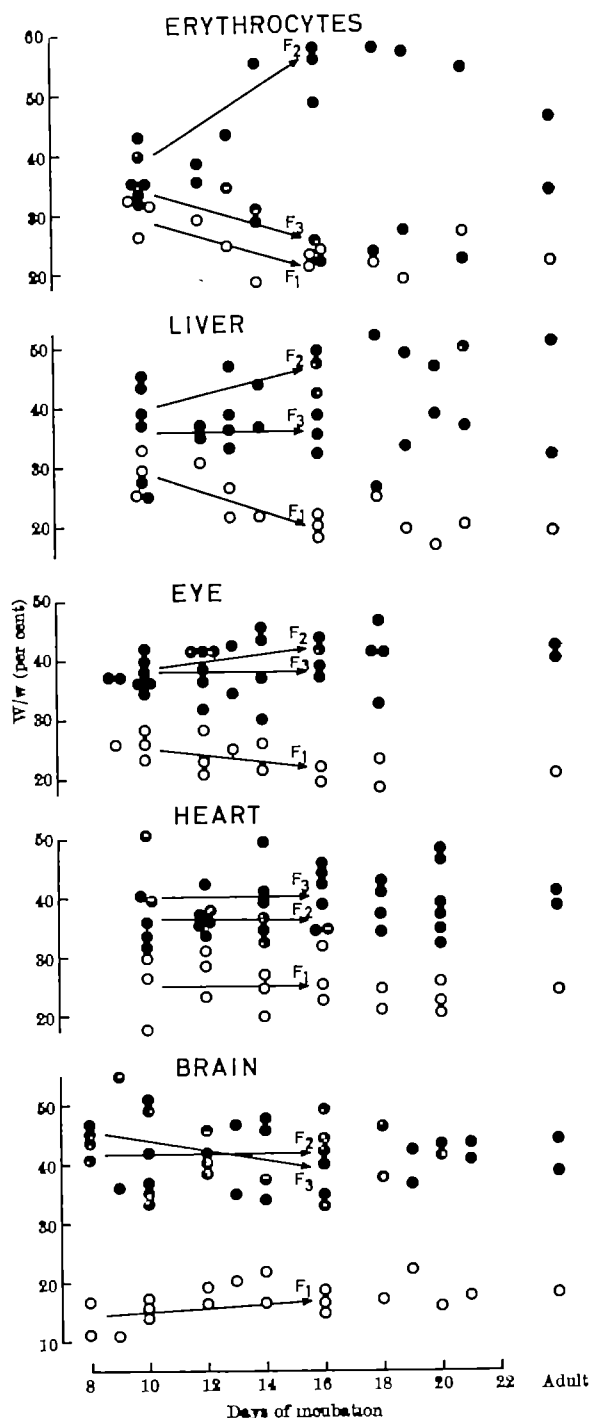

Fig. 2. The relative amount of the three histone fractions in different organs during the later development of the chick embryo. The change tendency for each fraction is marked by arrows. The designations are the same as in Fig. 1. Each point represents an estimation on organs from 20–100 embryos

the adult pattern is established before the 10th day. Whether this indicates that erythrocytes and liver continue to undergo differentiation after the other organs have ceased to do so is, of course, uncertain. We are well aware of the fact that the observed changes in the histone pattern may also reflect metabolic changes, particularly because the histones prepared for these estimations include cytoplasmic histones. However, the possibility that one of the ways in which histones influence differentiation is by masking RNA-templates should not be overlooked. Thus, RNA-associated basic protein in the cytoplasm of blastomeres from cleavage stages of sea-urchin

embryos disappears gradually with advancing development<sup>8</sup>, and it has been found in this laboratory that the non-incubated chick embryo has ribosome-associated basic proteins.

Finally, as can be seen in Fig. 2, the adult histone pattern is different in different organs. In erythrocytes and liver the relative amount of  $F_2$  is intermediate, while in the other organs  $F_2$  is very near in quantity to  $F_1$ . In electropherograms the histone pattern is different in erythrocytes, spleen and testes from chicken<sup>10</sup>.

### Benzyl Thiocyanate Taint in the Milk of Dairy Cattle Ingesting *Coronopus didymus* Sm.

AN objectionable flavour is found in the milk of dairy cattle which graze on pastures infested with the cruciferous weed *Coronopus didymus* Sm. (bitter cress or land cress)<sup>1</sup>. This taint is of considerable concern in Queensland and New Zealand where the weed is widespread during winter; unlike many other fodder or weed taints in milk, it cannot be removed during the manufacture of cream or butter<sup>1,2</sup>. The taint in milk is characteristically a burning flavour with a sharp odour, while in butter it is a burnt flavour with a burning after-taste.

In earlier investigations<sup>3,4</sup> glucotropaeolin, a mustard oil glucoside<sup>5</sup>, was found to occur in this plant. Benzyl cyanide, benzyl isothiocyanate, dibenzyl disulphide and benzyl mercaptan have been isolated as products of the enzymatic or chemical breakdown of the glucoside. None of these compounds was found to give rise to the characteristic taint when fed to dairy cattle<sup>1,2</sup>, or when added to taint-free milk.

Recently, Virtanen *et al.*<sup>6</sup> found that on crushing the seeds of the cruciferous weed *Lepidium sativum* L. and incubating the crushed seeds in water, benzyl isothiocyanate is the initial breakdown product of the glucotropaeolin which is present in the plant. The isothiocyanate, however, was found to isomerize rapidly in the incubated extract, to give benzyl thiocyanate. This isomerization, observed also in a related *Lepidium* species, was apparently carried out by an enzyme present in the crushed seeds.

Similar experiments have now been carried out on seeds from *C. didymus*. Gas chromatograms and infra-red absorption spectra of extracts of the crushed seeds, after chromatography on alumina, have indicated that benzylthiocyanate ( $\nu$ -SCN 2158  $\text{cm}^{-1}$ ) (ref. 7) is produced in *C. didymus* by isomerization of initially produced benzyl isothiocyanate. The isomerization was apparently complete within 15 min of mixing the powdered seeds with water.

The characteristic off-flavour has now been reproduced in the milk of dairy cattle by either drenching a dairy cow with benzyl thiocyanate dissolved in peanut oil or by the addition of benzyl thiocyanate to taint-free milk. When a dairy cow was fed 3 g benzyl thiocyanate, a taint developed in her milk within 2 h, became very strong after 4–6 h and disappeared within 24 h. The characteristic taint carried through to the derived cream and butter. Addition of

0.16 p.p.m. of benzyl thiocyanate to taint-free milk produced a detectable taint, whereas 4 p.p.m. gave a very strong taint to the milk, and the characteristic burning flavour to the cream.

There is the possibility that benzyl mercaptan may contribute to the associated taint in butter, as has previously been suggested<sup>8</sup>, since benzyl thiocyanate could be reduced to the mercaptan by cysteine or similar reducing agent, during the pasteurization of cream before the manufacture of butter.

Evaluation of flavour of the milk and products in these experiments was carried out by experienced dairy produce graders from the relevant Queensland and Commonwealth Government Departments.

This work was supported by a fellowship and an associated research grant from the Australian Dairy Produce Board.

### Mechanism of the Inhibitory Effect of Adenine Nucleotides on Porphyrin Synthesis by *Rhodospseudomonas spheroides*

EXCESS biosynthesis of porphyrins is strongly decreased by some adenine nucleosides and nucleotides (inosine, 5' AMP, 5' ADP, 5' ATP) *in vivo* as well as *in vitro*<sup>1–3</sup>. Experiments with *Rhodospseudomonas spheroides* have shown that ATP is the most active of these adenine derivatives, determining a more than 90 per cent inhibition<sup>4,5</sup> in a concentration of 3 m.moles/l. of medium. On the other hand, it was established that this effect is confined to the step of ALA formation<sup>3,6</sup>.

To explain this decrease of porphyrin synthesis we have first envisaged, on the basis of the tricarboxylic-glycine cycle of Shemin<sup>4</sup>, a negative feed-back reaction on ALA synthetase. Our recent experiments have shown that this hypothesis is not correct. In *Rhodospseudomonas spheroides* grown anaerobically for 24 h in the light in medium I of Lascelles<sup>7</sup>, ALA synthetase activity was even enhanced when ATP was added to the medium (Table 1).

Table 1. ALA SYNTHETASE ACTIVITY OF EXTRACTS IN MAXIMUM ALA FORMED PER MG PROTEIN OF EXTRACT\*

Exp.	Extracts of micro-organisms grown in presence of ATP (3 m.moles/l. of medium)	Extracts of micro-organisms grown without addition of ATP to the medium
1	66.6	18.3
2	45.0	11.4
3	23.0	4.3

\* 0.5 ml. extract was incubated for 30 min at 37° C and pH 7.4, with glycine, succinate, CoA, pyridoxal, Mg<sup>++</sup>, and ATP (following the technique of Grandik and Urate<sup>8</sup>).

We have therefore assumed that the adenylic derivatives enhance the formation of a physiological inhibitor of porphyrin synthesis, the existence of which in *Rhodospseudomonas spheroides* was reported by Kikuchi and colleagues<sup>7</sup>. This hypothesis seems to be confirmed by our experiments. *Rhodospseudomonas spheroides* suspended in Lascelles medium I to which ATP was added (3 m.moles/l. of medium) were incubated for 24 h semi-anaerobically, in the light. The micro-organisms were then gathered by centrifugation at 0° C and repeatedly washed with 0.9 per cent NaCl solution.

After freezing and thawing, or sonication, of the micro-organisms, extracts were prepared by diluted phosphate buffer (0.02 M, pH 6.8). These extracts added to a new suspension of *Rhodospseudomonas spheroides* significantly inhibited the porphyrin synthesis. Extracts prepared from *Rhodospseudomonas* incubated without ATP exerted no inhibitory effect (Table 2).

Table 2. PORPHYRINS SYNTHESIZED BY *R. spheroides* DURING 18 TO 24 H INCUBATION  
(In  $\mu\text{g}$  per ml. of medium)

Exp.	Without addition of extract to the medium	In presence of extract from <i>R. spheroides</i> incubated with ATP*	In presence of extract from <i>R. spheroides</i> incubated without ATP*
1	70.2	34.0	68.5
2	40.4	16.7	39.5
3	36.2	25.0	32.0

\* 1 ml. extract, containing 1 mg/ml. protein, was added to 10 ml. of Lasecelles medium I.

The experiments show clearly that *Rhodospseudomonas spheroides*, grown in a suitable medium containing 3 mmoles ATP, synthesizes to an increased degree an inhibitor of porphyrin which is extractable from the micro-organism by diluted phosphate buffer.

This inhibitor seems to be a protein and is presumably an enzyme. In fact, it is heat-labile and non-dialysable. Purification of this enzyme, which is in progress in our laboratory, will be necessary to establish its substrate. Our observations provide some evidence that the substrate may be succinic acid, one of the two simple precursors of porphyrins. Addition of succinate to *R. spheroides*, previously incubated in presence of ATP, re-establishes indeed to some extent the greatly decreased porphyrin synthesis. On the other hand glycine, the other precursor of porphyrins, is ineffective in this respect (Table 3).

Table 3. PORPHYRINS SYNTHESIZED BY *R. spheroides*  
(In  $\mu\text{g}$  per ml. of Lasecelles medium I)

Exp.	After 18 h incubation		After 24 h further incubation	
	Without ATP	With ATP*	With ATP* and succinate†	With ATP* and glycine‡
1	19.2	0.13	1.02	0.20
2	22.0	0.20	3.0	0.25
3	47.0	0.20	1.70	

\* 3 m moles/l. of medium.

† 0.001 moles/l. of medium.

‡ 0.005 moles/l. of medium.

A similar effect of succinate was observed when it was added to *R. spheroides* previously incubated with AMP. Our experiments seem to show that ATP and AMP added to *Rhodospseudomonas spheroides*, growing in Lasecelles medium I, anaerobically, in the light, enhance the formation of a presumably physiological inhibitor of porphyrin synthesis. This inhibitor seems to be an enzyme, the substrate of which remains to be established.

**Note added in proof.** In our latest experiments, using extracts obtained with a French press, which disrupts the cell membranes more completely than sonication or freezing and thawing, ALA-synthetase activity was not modified (or enhanced) after incubation of *Rhodospseudomonas spheroides* with ATP. These findings do not confirm the conclusions of our earlier observations.

## PHYSIOLOGY

### An Inhibitory Component of the Response to Distension of Rat Ileum

THERE is good evidence that the longitudinal smooth muscle of small and large intestine of rat, mouse, guinea-pig and rabbit is supplied with inhibitory nerves arising from intrinsic neurones which are probably components of the myenteric plexus<sup>1,2</sup>. These inhibitory nerves can be excited by transmural stimulation of segments of intestine<sup>3</sup>, by 'field' stimulation of strips of intestinal muscle<sup>4</sup>, or by ganglion stimulants such as dimethyl-4-phenylpiperazinium iodide (DMPP)<sup>1,2</sup>. The relaxation of the longitudinal muscle mediated by these nerves can always be observed in the presence of atropine, 1  $\mu\text{g}/\text{ml}$ , which blocks any muscarinic excitatory effects due to stimulation of cholinergic nerve fibres within the wall of the intestine. Since the inhibitory response is unaffected by concentrations of guanethidine and bretylium which block the relaxation in response to paravascular nerve stimulation, it seems likely that the intrinsic inhibitory system is distinct from the sympathetic system. The conditions which cause reflex activation of the intrinsic inhibitory neurones, *in vivo*, remain to be clarified.

An example of the response of rat ileum, in the presence of atropine, 1  $\mu\text{g}/\text{ml}$ , to transmural stimulation with pulses of 200  $\mu\text{sec}$  duration at 5/sec is shown in Fig. 1a. In this preparation, as described previously<sup>5</sup>, the relaxation was not maintained throughout the period of stimulation. At this frequency and at even lower frequencies which would be unlikely to cause a diminished output of transmitter, rhythmic contractions began again after 5–10 sec. On the cessation of stimulation the tone and amplitude of the contractions were greatly increased. Fig. 1b shows that a very similar response occurs following a small dose of the ganglion stimulant DMPP. During the present experiments we have found that isolated segments of rat intestine give a similar relaxation in response to an increase in intraluminal pressure (Fig. 1c).

Fig. 1. Rat ileum preparation in atropine, 1  $\mu\text{g}/\text{ml}$ . Tension recorded isometrically from longitudinal muscle. a, Response to transmural stimulation with 200- $\mu\text{sec}$  pulses at 10/sec; b, responses to 1  $\mu\text{g}/\text{ml}$ . DMPP; c, response to increased intraluminal pressure by 2 cm water.

Segments of rat ileum, 2 and 3 cm long, were set up in a modified Krebs solution<sup>6</sup>, in a 70-ml. isolated organ bath at 35° C. One end of the preparation was occluded by a knot of silk thread which was attached to the recording device while the other was tied to a J tube of the type described by Trendelenburg<sup>7</sup>. A platinum wire was passed through the J tube into the lumen of the gut for transmural stimulation. Responses to distension were elicited by introducing Krebs solution into the J tube so that the intraluminal pressure was increased by 1.5–3 cm water. In most experiments the tension in the longitudinal muscle was measured with a force transducer. In some experiments the length of the preparation was recorded with an isotonic lever. In all cases, an increase in intraluminal pressure caused relaxation of the longitudinal muscle. Only a small fraction (less than 0.2 g) of

Fig. 2. *a-c*, Responses of five different rat ileum preparations to increased intraluminal pressures of 2.5 cm water. All in atropine 1 µg/ml. *d* and *e*, in hexamethonium, 100 µg/ml, and guanethidine, 50 µg/ml. *f*, response of guinea-pig ileum, in atropine 1 µg/ml, for comparison with rat ileum.

the decrease in tension recorded under isometric conditions was due to the increased intraluminal pressure itself, which constituted a force acting in the opposite direction from that generated by the longitudinal muscle. The absence of any other mechanical artefacts was confirmed by experiments in which procaine, 500 µg/ml., was used to block the reflex response.

The fall in tension elicited by distension was transient. If the increased pressure was maintained, some preparations regained their normal tone after 50–100 sec and some developed tensions which were greater than those recorded during the control period. The tone and beat of other preparations remained below normal throughout the period of distension but there was always some recovery. When the intraluminal pressure was returned to atmospheric pressure again, the longitudinal muscle developed increased tension which resembled the rebound contractions following transmural stimulation and DMPP. Some examples of the response of different preparations of rat ileum in the presence of atropine (1 µg/ml.) to an increase in intraluminal pressure of about 1 min duration are shown in Fig. 2.

These responses of rat ileum differ markedly from those of the guinea-pig ileum, an example of which is shown in Fig. 2*f*. It is well known that distension of the lumen of the guinea-pig ileum causes increased tension and large rhythmic contractions of the longitudinal muscle (the preparatory phase of the peristaltic reflex<sup>6</sup>). Although this response was blocked initially by atropine, 1 µg/ml., it returned during prolonged exposure to the drug, as reported previously<sup>4</sup>. We have occasionally seen a brief relaxation or a delay before the onset of contractions when recording from guinea-pig ileum under isometric conditions. However, it seems likely that the response of this preparation to distension is dominated by excitation.

The initial fall in tension, subsequent recovery and rebound contraction of the rat ileum in response to distension were unaffected by atropine (10 µg/ml.), guanethidine (100 µg/ml.) and hexamethonium (100 µg/ml.). Relaxation in response to transmural stimulation was also resistant to blockade by these drugs. Both responses were blocked by procaine, 500 µg/ml. The only way in

which the response to distension differed from the response to transmural stimulation was in its time course. Although both relaxations were transient, relaxation in response to distension was sometimes of longer duration than the relaxation in response to transmural stimulation.

In some preparations, especially those in which the relaxation was followed by a rapid redevelopment of tension (Fig. 2*b*, *c* and *e*), it was possible to 'block' the response to transmural stimulation by interacting this stimulus with an increase in intraluminal pressure. If the intramural inhibitory nerves were stimulated submaximally during the early part of the recovery phase of a maximal response to distension there was little or no subsequent fall in tension.

The similarity of the responses to distension, transmural stimulation and DMPP suggest that these three types of relaxation may be mediated by the same efferent pathway. We suggest that the afferent fibres which are sensitive to distension of the lumen of the intestine synapse with inhibitory intrinsic neurones which supply the longitudinal muscle of rat ileum.

The receptors of this synapse was unlikely to be of the nicotonic type, since the response to distension is not blocked by hexamethonium. On the other hand, these inhibitory neurones appear to be excitable by cholinomimetic ganglion stimulants. It seems possible that they may be supplied with cholinergic terminals from other intrinsic neurones or from autonomic fibres.

### Characteristics of Excitatory and Inhibitory Synapses in the Central Nervous System of the Cat

ELECTRON microscopic investigations by Gray<sup>1,2</sup>, De Lorenzo<sup>3</sup> and Hamlyn<sup>4</sup> suggest that there are three types of patches of membrane density in the synaptic contacts of the central nervous system, of which only two are functional (Gray's type 1 and type 2). However, no criterion has yet been established to distinguish the excitatory synapses from the inhibitory ones. In the peripheral autonomic nervous system two types of synaptic vesicles (cholinergic and adrenergic) have been found, the former having a diameter of 500 Å with clear content, while the latter have a diameter of 1000 Å with granular cores<sup>5-7</sup>. So-called granulated vesicles have also been discovered by Shimizu<sup>8</sup> in the hypothalamus of mammals. Gray's classification hints that the type 1 synapse is excitatory, whereas the type 2 is inhibitory<sup>9</sup>.

In our experiments two different types of synaptic vesicle have been found in the somatic nervous system of the cat. The size and shape of each type of synaptic vesicles are quite different, making it easy to differentiate the excitatory synapses from the inhibitory ones. The thorax of a cat was opened under 'Nembutal' anaesthesia and a cannula was inserted into the ascending aorta

Fig. 1. Cross-section of dendrite in the molecular layer of the cat's cerebellum. The dendrite (D) is surrounded by several excitatory synapses (E), and only one inhibitory synapse (I). The bar indicates 0.1  $\mu$ .

through the left ventricle. The blood of the whole body was washed out through the cannula by Locke's solution. After confirming that the whole body had been perfused (no blood from the veins) the Locke's solution was replaced by formalin solution. The osmolarity and hydrogen ion concentration of the fixative were regulated carefully with sucrose and other chemicals. After the fixation of the whole body of the cat, the skull was opened. Thin sheets of the cerebellum were cut off. Small pieces of the out cerebellum were immersed in an ice-chilled osmium tetroxide solution for about 2 h. After routine dehydration and embedding thin sections were made by an LKB ultramicrotome. Electron microscopic investigations were carried out by an Akashi 80 electron microscope. The thick sections were used for the location of the molecular and Purkinje cell layers of the cerebellum using a phase-contrast microscope.

Two quite different types of synapses were easily identified. Fig. 1 shows a dendrite (D) in the molecular layer of the cerebellum of the cat. The dendrite is surrounded by several synapses, of which one type (E-type) contains spherical vesicles having a diameter of about 400 Å, while the other type (I-type) is filled with ellipsoidal vesicles, and the size of the latter vesicles is smaller than the former. The whole surface of the soma of Purkinje cells in the cerebellum is exclusively surrounded by

numerous synapses which have ellipsoidal vesicles in them. It has also been suggested electrophysiologically that the soma of Purkinje cells is densely innervated by inhibitory synapses. So it may be concluded that the synapses containing ellipsoidal vesicles are inhibitory in nature and correspond to Gray's type 2. The dendrites of the outermost part of the molecular layer of the cerebellum are innervated almost exclusively by E-type synapses which are equivalent to Gray's type 1. Electrophysiologically it is highly probable that the E-type synapses are excitatory<sup>3</sup>. Fig. 2, left, shows the schematic representation of a dendrite (D) and its synapses in the molecular layer of the cat's cerebellum. Two inhibitory synapses are indicated (I), while the others are all excitatory. Fig. 2, right, illustrates schematically two types of synapses, the one, the excitatory (E), the other, the inhibitory (I).

The method of synapse differentiation based on the shape and size of synaptic vesicles has enabled us to distinguish quite easily excitatory and inhibitory synapses on the surface of neurones in the central nervous system of mammals. The microtopography of different types of synapses of neurones in the central nervous

system, including the spinal cord, is being carried out. The identification and classification of various types of neurones in the central nervous system may be possible.

### An Electronically Modified Wet Spirometer

In a recent investigation of respiratory muscles, recordings were made simultaneously from multiple indwelling electrodes, along with spirometric tracings, so that electrical activity could be examined in a series of conscious rabbits during quiet respiration. The electrical signals from the muscles and the spirometric tracing are shown on a film record (Fig. 1). Attention is directed especially to the spirometric tracing which appears as a horizontal band which widens with expiration and narrows with inspiration. A primary interest was to secure an accurate reflexion of the movement of air into and out of the lungs of the rabbit, a factor dependent on the accuracy of the spirometer. Although many spirometers are available, a simple, inexpensive electronic modification of a wet spirometer (400-c.c. Phipps and Bird spirometer, Richmond, Va.) was developed (Fig. 2). The electronic modification of the spirometer, its application, and a method devised to determine its latency from the subject of this communication.

The spirometer is designed so that its lower cylinder can be filled with water and its inverted floating cylinder filled with air. A metal tube within the lower cylinder is connected to an external primary T-tube and carries respiratory gases above the water line and into the

Fig. 2. Schematic representation of longitudinally sectioned dendrite (left) and two types of synapses, excitatory (E) and inhibitory (I).

Fig. 1. An electromyogram from separate muscular slips of the diaphragm co-ordinated with spirometry (Sp) and 10-msec time marker (T). The spirogram appears as a horizontal band which widens with expiration and narrows with inspiration

floating cylinder. A secondary T-tube is inserted into another vessel containing soda-lime for the absorption of carbon dioxide. The two T-tubes are interconnected by a rubber tube 10 cm long and 5 mm inside diameter. The other end of the primary T is connected to an oxygen tank by means of a similar rubber tube. Another tube 35 mm long and 5 mm inside diameter leads from the remaining arm of the secondary T to the stem of a Y-tube the arms of which are equipped with a pair of rubber tubes 7.5 cm long. Flexible plastic foetal catheters 4 mm inside diameter and 5 cm long are inserted into the tips of the last-mentioned tubes. The catheters, which are passed into the rabbit's nares during recording sessions, are coated with a topical anaesthetic ointment ('Tromothane hydrochloride') which serves to desensitize the nasal passages as well as to prevent any possible leakage of air around the catheters.

The nasal catheters are well tolerated and the animal will rest in the sternal recumbent position for long periods of time. In an earlier experiment a dental plate with an embedded tube for the passage of air was moulded to fit into the mouth of the rabbit and was in turn connected to the spirometer. The respiratory excursion of the spirometer was nil and it was found that the rabbit breathed mainly through its nose. It was therefore imperative to employ the nasal route.

Under experimental conditions, the animal inspires 50–75 ml. of oxygen, moving the floating cylinder 1–1.5 cm during respiration. The frequency of the respiratory cycle varies from 40 to 50 per min. No evidence of resonance was detected in the system at this frequency and within the range of the volume of gas exchanged.

For the purpose of recording respiratory movements, a modification of the spirometer was devised in order to produce a fluctuating electrical signal capable of translating the excursions of the floating cylinder on a cathode ray oscilloscope. Two small inductance coils 1.5 cm in diameter and 1 cm wide were constructed. Each coil consisted of 150 turns of No. 28 enamel copper wire wound on a plastic spool. One of the coils was passed over a vertical rod which ascends from the floating cylinder and was securely fastened to it 1.5 cm above the top of the cylinder (Fig. 2). Preliminary tests showed that the weight of this coil does not affect the mechanical properties of the spirometer. The second coil was also passed over the vertical rod of the floating cylinder but was fixed in place, independent of that rod, by means of a plastic clip attached to the upright pulley support, 7.5 cm above the lower or movable coil. This arrangement was such as not to interfere in any way with the vertical movement of the rod and cylinder.

In preparing to use the apparatus for experimentation on a rabbit, sufficient oxygen is passed into the spirometer so that the movable coil approaches to within 3–4 cm of the fixed coil. An a.c. signal generator adjusted to

Fig. 2. An electronically modified wet spirometer. produce a 5,000-cycle sine wave was connected to the mobile coil. The fixed or pickup coil was connected to one channel of a dual beam oscilloscope. By variable inductive coupling the fixed coil picks up from the moving coil the 5,000-cycle signal applied to it. Since the output from the fixed coil is proportional to its distance from the moving coil, it follows that the electrical output is proportional to the volume of air fed into the spirometer during each respiratory cycle.

It was deemed important to determine the factor of latency in the spirometer. A method which was devised to determine any latency consisted of setting up the spirometer in the manner described here (Fig. 2) except that the nasal catheters were inserted into a rubber balloon instead of the nose of a rabbit (Fig. 3). The balloon was

NH band at  $3,300\text{ cm}^{-1}$ , a shifted, sharpened CO band at  $1,700\text{ cm}^{-1}$ , and a split  $\text{COO}^-$  band at  $1,550\text{--}1,650\text{ cm}^{-1}$ . The diffuseness of the monohydrate bands indicates a low degree of order, and this conclusion is supported by the crystal densities and solubilities. X-ray diffraction analyses (performed by Prof. T. Doynes of Villanova University) give densities of 1.372 and 1.312 and molecular weights of 348 and 370 (calculated: 349 and 367) for the anhydrate and monohydrate. The anhydrate has lower solubility in water, dimethylformamide, dimethylacetamide, dimethylsulphoxide and acetonitrile. It does not change into the monohydrate when exposed to an atmosphere of 100 per cent humidity, and undissolved crystals remain anhydrous after 24-h suspension in water.

A remarkable difference in  $\beta$ -lactam lability stems directly from the association of a molecule of hydrate water with the penicillin molecule in the solid crystal (Table 1). This difference, established by hydroxamate formation<sup>7</sup>, activity against *E. coli*, and infra-red analysis, is also demonstrable at room temperature and under various conditions of heat plus high humidity, such as autoclaving.

Table 1.  $\beta$ -LACTAM CLEAVAGE IN CRYSTALLINE AMPICILLIN

°C	H	Per cent hydrolysis	
		Anhydrate	Monohydrate
70	66	0	39
70	160	0	61
107	18	2	66
107	90	1	79
135	0-25	4	55

It is apparent from this study that, despite very firm binding within the hydrate crystal, the water molecules are sufficiently free to participate in a solid-state hydrolytic reaction. Whether the reaction is intramolecular or intermolecular, or whether this concept even has validity in such a case, will depend on more precise information on the site of water attachment and the structure of the crystal.

### Effect of 3,4-Benzpyrene on the Formation and Hydrolysis of Conjugates

REPORTS in the literature postulating the presence of sex differences in conjugation, especially in glucuronide conjugation, led us to demonstrate this point on the Wistar strain of rats by raising the conjugation capacity with a carcinogen, 3,4-benzpyrene (Inscoc and Axelrod<sup>1</sup>). The purpose was to elicit the possible differences more clearly. In the same connexion, we studied both uridine diphosphate glucuronic acid (UDPGA) transferase and total conjugation, as we had found in earlier experiments that these processes do not necessarily have a parallel course. We also observed how, when a carcinogen of this kind shifts the conjugation activity to another level, certain hydrolytic enzymes associated with it, such as  $\beta$ -glucuronidase and arylsulphatase, also undergo a change. In addition, we used Sprague-Dawley rats from another laboratory besides our own Wistar strain.

The groups of Wistar rats from our own laboratory and Sprague-Dawley rats obtained from outside comprised 5-8 animals each.

UDPGA-transferase and *o*-aminophenol conjugation on the slice were analysed by the same methods as in earlier experiments<sup>2</sup>. Acetone powder was prepared from the tissues for the determination of hydrolytic enzymes. The powder was washed once with acetone and dried on phosphorus pentoxide in vacuum. The acetone-dried powder was then dissolved in water and the water-soluble and insoluble fractions were separated by centrifuging the suspension at  $18,000g$  for 30 min. Water-soluble sulphatases A and B, 4-nitrocatecholsulphate as substrate and  $\beta$ -glucuronidase were determined from the aqueous phase. *p*-Nitrophenylsulphate was used as the substrate of fraction C. The methods are modifications of those described in earlier studies<sup>3</sup>.  $\beta$ -Glucuronidase was determined according to Fishman, Springer and Brunetti<sup>4</sup>. The  $\beta$ -glucuronidase remaining in the fraction that was insoluble in water was determined in addition to sulphatase C.

The results are presented in Tables 1, 2 and 3. UDPGA-transferase activity rose distinctly under the influence of benzpyrene in both male and female rats. This applied to both our own Wistar strain and the Sprague-Dawley animals. No notable differences were observed between the activity of the different rat strains and no sex differences were seen in the elevated activities. The total conjugation of *o*-aminophenol in the liver was lower for both the male and female Sprague-Dawley rats than for the Wistar strain. In contrast, the activities in the duodenum did not differ. The situation in the kidneys appeared to be the same as in the liver. 3,4-benzpyrene did not produce a distinct increase in total conjugation in the Wistar strain, but the conjugation in the Sprague-Dawley rats rose to nearly the level of the Wistar animals. It had no major influence on hydrolytic enzymes. The sulphatase A + B fraction in the liver was roughly twice as great for the female as for the male rats. No definite sex differences in the strength of the hydrolysis of the conjugates were noted elsewhere. Most of the  $\beta$ -glucuronidase could be analysed from the water-soluble phase. This method also failed to demonstrate any difference between the animal strains used. On the other hand, it was possible to confirm

the observation that benzo[a]pyrene has an effect on the transferase activity of UDPGA. An increase occurs also in the total conjugations.

The increase in conjugation capacity caused by this carcinogen is a theoretically interesting defensive reaction by the organism against a noxious agent. This manifest sex difference displayed by hydrolytic enzymes in fraction A+B is evidence of the role of regulation by hormonal factors in the conjugation processes. It may be said that the results obtained in the present study also show how different results can be obtained not only with different animal species but also with different strains of the same species.

## HISTOCHEMISTRY

### An Evaluation of the Histochemical Demonstration of Certain Pyridine Nucleotide-linked Dehydrogenases

Farber, Sternberg and Dunlap<sup>1,2</sup> have questioned the validity of histochemical techniques for the demonstration of pyridine nucleotide-linked dehydrogenases. They have argued that since the actual reduction of the tetrazole results from its interaction not with a dehydrogenase but with a diaphorase (tetrazole reductase) specific for NADH or NADPH, strictly speaking the reactions are specific only for NADH- or NADPH-tetrazole reductase. Qualitative evidence was presented to show that of five pyridine nucleotide-linked dehydrogenases studied in rat kidney, only two staining patterns emerged, depending on whether the dehydrogenase required NAD<sup>+</sup> or NADP<sup>+</sup> in the reaction medium. While admitting that the tetrazole reductase was responsible for the actual reduction of tetrazole at the expense of reduced pyridine nucleotide, other workers<sup>3,4</sup> have concluded from similar experiments that each dehydrogenase has its own characteristic pattern of distribution. This point of view has been extensively accepted, but anomalies of formazan localization within the cell<sup>5,6</sup> and the observed escape of soluble dehydrogenases into the incubation medium<sup>7-12</sup> support the original conclusions of Farber and his colleagues.

The development of quantitative histochemical methods<sup>11,12-14</sup> for the estimation of dehydrogenase activity in which formazan production from neotetrazolium has been related to the total residual nitrogen of the stained, extracted tissue section has enabled glucose-6-phosphate (G6P) and 6-phosphogluconate (6PG) dehydro-

genases to be studied in frozen sections of rat liver. Although G6P dehydrogenase, or, more accurately, the G6P-neotetrazolium reductase enzyme complex, is fairly active in rat liver, preincubation of sections in 0.1 M glycylglycine buffer pH 7.6 for only a few minutes before incubating in the full reaction medium abolished the activity. It has been shown<sup>15</sup> that about 70 per cent of the total nitrogen of frozen sections of rat liver was lost during the first 5 min of incubation in an aqueous medium. In addition, direct measurements have established that G6P- and 6PG-dehydrogenases escaped into the incubation medium and reduced NADP<sup>+</sup> at the expense of substrate outside the section<sup>11,12</sup>, while in the preincubation experiments the enzymes were lost during the preincubation. These data suggest that cells of different types might be expected to show formazan deposition more in proportion to the relative activities of NADPH-tetrazole reductase at rate-limiting concentrations of NADPH than in proportion to their original dehydrogenase content.

This possibility has been tested in the following experiments. Rats were killed by asphyxiation with nitrogen, and pieces of liver and heart about 4 mm<sup>3</sup> were frozen in cold tubes<sup>17</sup> at -70° C and in hexane<sup>18</sup> at the same temperature respectively. Sections were cut in a cryostat at -25° C, the knife being chilled with solid carbon dioxide<sup>19</sup>, and mounted near the ends of microscope slides. For quantitative experiments the incubation media were as follows.

(a) *G6P-neotetrazolium reductase*: 0.1 M glycylglycine buffer, pH 7.6; NADP<sup>+</sup>, 2.0-2.5 mg/ml.; G6P, 4.5 mM.; neotetrazolium chloride, 1.5 mM.; cyanide, 10 mM.

(b) *6PG-neotetrazolium reductase*: the medium was identical, but 6PG was substituted for G6P at the same molarity.

(c) *NADPH-neotetrazolium reductase*: both substrate and NADP<sup>+</sup> were replaced by NADPH (2.0-2.5 mg/ml.). Sections were incubated singly at 37° C in microcells<sup>14</sup> containing 0.18 ml. incubation medium (internal diameter of cell, 8 mm). Sections of both tissues were mounted adjacently on the same slide and incubated together (double technique) in larger microcells containing 0.35 ml. incubation medium (internal diameter, 12.5 mm). Formazan was produced exclusively on the sections and not in the incubation medium. After washing and drying, the stained sections were quantitatively analysed<sup>13,14</sup>.

As shown in Table 1, the values found for the activities of G6P- and 6PG-neotetrazolium reductases were much higher in heart sections which were incubated with liver sections than when the heart tissue was incubated on its own. NADPH-neotetrazolium reductase was equally active in sections incubated either by the single or by the double technique. Control sections incubated in the absence of substrate or NADPH gave negligible reactions, and the activities were too low to measure.

Similar effects have been demonstrated qualitatively under slightly modified conditions. In recent histochemical studies nitro-blue tetrazolium<sup>20,21</sup> and tetranitro-blue tetrazolium (TNBT)<sup>22,23,24</sup> have been generally preferred to neotetrazolium on account of their greater ease of reduction and the fineness of the corresponding formazan

deposits, but the high degree of substantivity which is shown by the formazans makes these tetrazoles unsuitable for quantitative studies of the kind described. In view of the widespread use of these compounds, experiments have been carried out in which sections of rat liver have been either incubated alone or pretreated with 0.15 M saline for 5 min before being incubated singly or with untreated sections. The incubation media contained 0.5 mM TNBT, 0.1 M phosphate buffer pH 7.6, NAD<sup>+</sup> or NADP<sup>+</sup> (2.0–2.5 mg/ml.) and 50 mM substrate. Substrates tested with NAD<sup>+</sup> were DL-lactate, DL-β-hydroxybutyrate, L-glutamate, α-glycerophosphate and DL-malate; substrates tested with NADP<sup>+</sup> were DL-isocitrate, G6P and 6PG. NADH- and NADPH-TNBT reductases were also studied, the levels of reduced pyridine nucleotides being 2.0–2.5 mg/ml. For lactate, β-hydroxybutyrate and NADH-TNBT reductases the staining time was 15 min; for all other enzyme complexes the staining time was 60 min. The reactions were carried out at room temperature.

Preincubation in saline had no detectable effect on the activity of NADH-TNBT reductase; similar results were found with NADPH-TNBT reductase, but in some experiments very slight losses of enzymatic activity may have occurred. Without exception, all substrate-linked enzyme complexes examined showed extensive or complete loss of activity following incubation in saline. The degree of recovery of enzymatic activity by saline-pretreated sections incubated together with untreated sections in the same microcells depended on the particular enzyme studied. Of the NAD<sup>+</sup>-linked enzyme complexes, extensive recovery was obtained in the presence of glutamate, and some recovery was shown in the presence of lactate or α-glycerophosphate. Neither malate nor β-hydroxybutyrate caused any apparent recovery. In the case of the three NADP<sup>+</sup>-linked systems tested, significant deposition of formazan was found associated with all the saline-pretreated sections.

Formazan production by frozen sections of heart muscle was low in the presence of either G6P or 6PG as substrate, but was considerably increased by incubating heart tissue with an active section of frozen liver simultaneously in the same solution. Substrate-linked TNBT reduction was sharply decreased or even abolished by preincubation procedures, but enzymatic activity was partially restored in certain cases by incubating together with untreated sections in the same solution. Qualitative<sup>7,8</sup> and quantitative<sup>10,12</sup> investigations of lactate dehydrogenase have indicated that this enzyme is substantially lost into the incubation medium from fresh frozen sections; it has also been quantitatively shown that G6P dehydrogenase<sup>8,11,12</sup> and β-hydroxybutyrate dehydrogenase<sup>12</sup> are lost under similar conditions. The results recorded here strongly suggest that the dehydrogenases escaped rapidly from the sections into the incubation medium, where substrates were oxidized with the concomitant reduction of pyridine nucleotide. The reduced pyridine nucleotide diffused back to the sections, and was oxidized by the appropriate tetrazole reductase at the expense of a tetrazole. It is therefore inadvisable to compare pyridine nucleotide-linked dehydrogenase activities in cells on a section on the basis of the intensities of formazan deposition, since the amount of formazan produced is not necessarily related to the amount of dehydrogenase activity originally present in the cells. Farber<sup>7</sup> has pointed out the importance in histochemical investigations involving the use of tetrazoles of showing that the dehydrogenase and the reduced pyridine nucleotide coenzyme which it generates remain bound to the tissue during incubation. Since the retention of enzymes may depend to some extent on the method of tissue preparation and will certainly depend on the subsequent treatment, the advisability of testing dehydrogenase systems under consideration for loss of enzymatic activity either by the techniques described or directly or both cannot be overstressed.

### Non-specific Alkaline Phosphatase Activity of Evaginating Epithelia

NON-SPECIFIC alkaline phosphatase activity has been demonstrated in the developing central nervous system, eye, lung and the allantois of the human embryo by Rossi *et al.*<sup>1</sup>, in the thyroid of the rat by McAlpine<sup>2</sup>, in the central nervous system, eye, ear and other sites in the chick embryo by Moog<sup>3</sup> and also in the pituitary and thyroid by Kaneko<sup>4</sup>. All the structures which show a high level of activity of this type develop by a process of evagination from an epithelium, and it has been suggested that alkaline phosphatase activity may be found in all epithelial evaginations during organogenesis<sup>5</sup>. No special examination of the association between phosphatase activity and evagination has been carried out, however. Forty-two chick embryos of known incubation time which formed a graded series from 30 h to 6 days were fixed in 70 per cent ethyl alcohol at 20° C. This method of fixation was found to be the most satisfactory and convenient. Whole embryos were embedded in paraffin wax and serial sections cut at 10μ. Alkaline phosphatase activity was demonstrated by means of an azo-dye method as described by Pearce<sup>6</sup>. The incubation period was 1 h.

Alkaline phosphatase activity was noted in the invaginating neural tube and its derivatives, the cerebral hemispheres, neurohypophysis and primary optic vesicle, and subsequently in the margins of the choroid fissure and the secondary optic vesicle. The renal tubules, dorsal and

ventral portions of the myotomes, biliary ducts, gall bladder, dorsal and ventral pancreatic anlagen likewise exhibit a high enzymatic activity. During the development of the ear, phosphatase activity was found in the otic vesicle, ductus endolymphaticus, lagema, semi-circular canal pouches, anterior recess of the utricle and ampullae. High levels were also found in Rathke's pouch, the anterior portion of the mesobranchial groove from which the thyroid is derived, the posterior laryngo-tracheal portion of the mesobranchial groove and afterwards in the trachea, mesobronchi, and entobronchi. Similar levels of phosphatase activity may be found in similar sites in the rat.

Further, when bronchial buds from a foetal rat were explanted *in vitro* and cultured for 4 days, new growth of irregular evaginating tissue also showed alkaline phosphatase activity. Under these conditions, the enzyme must have been formed by the evaginating tissue.

In all the evaginations examined, alkaline phosphatase activity was found during the active stage of the process, this activity being of a transient nature and disappearing as each evagination approached completion and was located on the concave aspect of each structure examined.

I thank Prof. J. D. Boyd for the facilities provided by the Department and Dr. P. R. Lewis for his suggestions. The investigations were supported by a grant from the H. E. Durham Fund of King's College, Cambridge.

## PATHOLOGY

### Behaviour of Intracerebral Autografts of Mouse Tail Skin pre-treated with a Single Application of 20-Methylcholanthrene

THURBORN grafts of tail skin from 30 mice of various strains and both sexes were implanted intracerebrally in an attempt to produce an expanding, space-occupying, intracranial lesion, and to investigate its effect on the surrounding brain, with particular reference to 'cerebral oedema'. The autografts, which were cut with a Castroviejo keratome set to a thickness of 0.2 mm, measured approximately 3 mm × 1 mm. Immediately after removal they were inserted into the right cerebral hemisphere with a blunt probe, through a small hole made over the lateral aspect of the skull with a dental burr. All operative procedures were performed under 'Nembutal' anaesthesia.

The grafts survived, and in most of the mice killed after 2-4 months had given rise to small intracerebral dermoid cysts containing non-laminated debris including keratin and hair shafts (Fig. 1). The implants were not associated with recognizable neurological signs during life. After 8-10 months most cysts showed atrophy of the epidermal lining and a varying degree of obliteration by a surrounding fibro-granulomatous and to a lesser extent gliotic reaction. It appeared that the cysts neither underwent continuous enlargement for more than 4 months nor had pronounced effects on the surrounding brain.

One of us<sup>1</sup> showed that the application of a single, minute dose of 0.1 per cent 20-methylcholanthrene (MCA) in acetone to a 10 mm × 3 mm strip of mouse tail

Fig. 1. Intracerebral dermoid cyst containing non-laminated debris (haematoxylin and eosin × 35)

Fig. 2. Intracerebral cyst containing compact laminated keratin (haematoxylin-Van Gieson × 35)

skin (equivalent to approximately 5 µg MCA per graft) accelerated the growth of the treated skin, but only when it was transplanted into another site (subcutaneous tissues of the flank); further, in the walls of some of the resultant cysts, keratinizing squamous carcinomas developed. If the treated tail skin was left *in situ*, repeated painting with similar or larger doses of MCA did not result in tumour formation.

We repeated these experiments on 24 mice, substituting intracerebral for subcutaneous transplantation, either 0.5 h or 48 h after painting with the same dose of MCA in acetone; in the 48 h group the treated site was covered with a glass tube. Control experiments on 12 mice using tail skin painted with acetone only gave results identical to the original experiments using untreated skin. In contrast, the growth of the MCA-treated grafts was accelerated and after 4 weeks prominent epithelial-lined cysts filled mainly with compact laminated keratin had developed (Fig. 2). Within 2 weeks there was a greatly increased number of mitoses in the basal layer of the cyst lining, as shown by the injection of colchicine (0.2 mg/100 g body-wt.) 6 h before death. Of the 9 mice killed between 4 and 12 months after transplantation, only 3 appeared normal before death, and these showed obliterated intracerebral cysts on histological examination. The remaining 6

Fig. 3. Keratinizing squamous carcinoma in the wall of a cyst (haematoxylin and eosin,  $\times 150$ )

Fig. 4. Well-differentiated astrocytic glioma at site of implantation (haematoxylin and eosin,  $\times 150$ )

mice showed marked loss of weight and akinesia and in 3 there was swelling of the cranium; 3 animals showed histological squamous carcinoma in the walls of the cysts (Fig. 3); in 2 the grafts were replaced by an abnormal cellular proliferation which resembled astrocytic glioma (Fig. 4); and one showed a lipogranulomatous reaction which also included undifferentiated neoplasm. In all the 6 animals with tumours the surrounding brain tissue showed the histological features of well-marked oedema and consecutive gliosis; similar but less pronounced changes developed around the non-neoplastic cysts. There were no detectable differences between the grafts transplanted 0.5 h and 48 h after MCA treatment.

It is shown, therefore: (1) Pre-treatment of small Thiersch grafts of tail skin with a single minute dose of MCA before intracerebral transplantation frequently induces an expanding intracranial cystic lesion. (2) In some instances squamous carcinoma develops in the transplanted skin. (3) Reactive and sometimes neoplastic changes occur in the adjacent brain tissue.

### Demonstration of 5-Hydroxytryptamine in Blood Platelets by Electron Microscope Autoradiography

MAMMALIAN blood platelets are known to contain 5-hydroxytryptamine (5-HT) and to concentrate 5-HT added to platelet-rich plasma *in vitro*<sup>1</sup>. Hughes and Brodie<sup>2</sup> suggested that 5-HT existed in an unbound form in the platelet. The maintenance of increased platelet 5-HT was believed to be best explained by the presence of an active transport system for 5-HT<sup>3,4</sup>. The finding that the amount of 5-HT in platelets is related to the content of adenosine triphosphate (ATP) has led to the suggestion that the amine is bound to ATP<sup>4</sup>, and investigations using density-gradient centrifugation of disintegrated platelets have demonstrated a fraction containing most of the 5-HT and ATP<sup>5</sup>. More recently, in experiments with platelets disrupted ultrasonically and subjected to differential centrifugation 80 per cent of the 5-HT was recovered in the sedimented fraction, suggesting that 5-HT was bound within granules<sup>6</sup>.

New methods for improving autoradiographic resolution and sensitivity<sup>7</sup> suggested that it should be possible to investigate the localization of platelet 5-HT at the ultra-structural level. To determine 5-HT loss from platelets during the fixation and dehydration used for electron microscopy 5-HT-3'-<sup>14</sup>C creatinine sulphate (specific activity 32 mc./mmole obtained from the Radiochemical Centre, Amersham) was dissolved in 0.15 M sodium chloride, and incubated with rabbit platelet rich plasma (PRP) according to the method of Hardisty and Stacey<sup>1</sup>. PRP was obtained by differential centrifugation after collection of carotid artery blood in 1/10 volume of citrate solution<sup>8</sup>. PRP specimens contained 150–250,000 platelets per cu.mm. The final concentration of 5-HT (expressed as free base) was 1.5  $\mu$ g/ml. PRP. After incubation for 90 min at 37° C the PRP was centrifuged, the supernatant plasma was decanted, and the platelet button was resuspended in 1 ml. cold 0.15 M sodium chloride. After further centrifugation the sodium chloride solution was decanted. 1.1 ml. of 0.02 N hydrochloric acid was added to the platelet button which was frozen and thawed twice. Aliquots of hydrochloric acid were plated on aluminium planchets and counted in an end-window Geiger-Müller counter, to determine the amount of 5-HT taken up by the platelets. To determine loss during fixation and dehydration the platelet button was fixed at 4° by the procedures indicated in Table 1, and afterwards dehydrated in graded alcohols, also at 4° C. Aliquots of fixative and alcohols were taken to determine 5-HT activity as a fraction of the total activity<sup>9</sup>. Representative 5-HT loss is shown in Table 1.

PRP for electron microscopy was incubated for 40 and 90 min with tritiated 5-HT creatinine sulphate (final concentration 1.5  $\mu$ g/ml.) and centrifuged at 4° C to obtain a platelet button (the tritiated 5-HT creatinine sulphate was supplied by Dr. E. A. Evans, Radiochemical Centre, Amersham, Bucks. Specific activity 7.7 c./mmole. Radiochemical purity 90 per cent. At least 80 per cent of the tritium was present in the indole ring). The platelets were resuspended in chilled 0.15 M sodium chloride and

Table 1. PERCENTAGE LOSS OF PLATELET 5-HT DURING FIXATION AND DEHYDRATION

Fixative	Loss in fixative	Loss in 0.1 M phosphate buffer wash Buffer wash unnecessary	Loss in alcohols	Total
1% Osmium tetroxide in Caulfield's buffer (30 min, 4° C)	13.0			20.3
3% Glutaraldehyde in 0.1 M phosphate buffer (40 min, 4° C)	2.5	1.5	19.0	23.0
3% Glutaraldehyde in 0.1 M phosphate buffer with 9% sucrose (40 min, 4° C)	2.2	3.3		
3% Glutaraldehyde (30 min) washed with 0.1 M phosphate buffer, followed by 1% osmium tetroxide (10 min)	10.0	1.8		

recentrifuged, and the sodium chloride was removed. Platelet buttons were then fixed as indicated in Table 1, with osmium tetroxide, glutaraldehyde or glutaraldehyde followed by osmium tetroxide. After dehydration in graded alcohols the tissue was embedded in 'Araldite'. Pale gold sections were cut on a Huxley (Cambridge) microtome, and processed for autoradiography by the method of Salpeter and Bachmann<sup>7</sup> using Kodak NTE emulsion. In certain cases sections were prepared according to the method of Koehler *et al.*<sup>10</sup> using standard glass slides to which NTE emulsion was applied with a pipette and then drained. The slides were dried in air, placed in boxes, and then exposed for 3-6 weeks in a light tight metal canister, containing silica gel, in an atmosphere of nitrogen. Slides were developed in Kodak 'Dektol' after gold intensification<sup>8</sup>. Sections were examined in a Philips '100B' electron microscope at 60 kV.

Background silver grains on control sections free of radioactivity were negligible in number. Silver grains were evident over platelets containing radioactivity (Fig. 1). The proportion of grains over platelets was compared to the area of the print occupied by platelets, as estimated by the method of Chalkley<sup>11</sup>. In three different fields the percentages of the total grains in the field which were over platelets were 91, 90 and 88 (mean number of grains per field: 225). These compare with percentage areas occupied by platelets of 58, 61 and 57 respectively. The difference ( $P < 0.01$ ) indicates a significant concentration of radioactivity within platelets. Developed silver grains were found in relation to dense granules, throughout the hyaloplasm, and at or adjacent to the limiting membrane (Fig. 2). The possibility that movement of 5-HT occurred during fixation and dehydration precludes any firm conclusion about platelet 5-HT localization, but experiments are in progress to eliminate or minimise such movement during processing.

Since aldehydes are known to form a tetrahydro-4-carboline derivative with 5-HT<sup>12</sup>, it is of interest that glutaraldehyde fixed platelets lost 5-HT mainly during alcohol dehydration, while osmium fixation resulted in a much larger loss during fixation. Although losses occurred at different stages the distribution of developed silver grains appeared to be similar in each case.

### Beneficial Effect of Oxytetracycline in Cortisone-induced Wasting Disease

INJECTION of hydrocortisone into new-born mice results in the development of a wasting syndrome similar to that seen in mice after neonatal thymectomy<sup>1</sup>. McIntire *et al.*<sup>2</sup> suggested that the wasting disease seen in neonatally thymectomized mice is associated with an infectious process as the wasting syndrome does not appear in neonatally thymectomized germ-free mice. Administration of antibiotics to neonatally thymectomized rats has been shown to influence favourably the subsequent development of wasting disease in these animals<sup>3,4</sup>.

During experiments performed to investigate the effects on various immunologic functions of both neonatally cortisone-treated and neonatally thymectomized C3H and C57BL mice some animals from both groups received oxytetracycline in their drinking water. Groups of inbred C3H and C57BL mice of both sexes were given 0.1 mg/g doses of hydrocortisone acetate at 4 days of age. Littermates were thymectomized or sham-thymectomized at 1-2 days of age. Treated animals were caged with two groups of foster mothers, one of which had 5 mg per cent oxytetracycline added to the drinking water. The animals were weaned after 20-30 days.

All the animals receiving hydrocortisone initially showed retardation of development, evidenced by subnormal weight gain and poor growth of hair. However, the animals nursed by mothers receiving oxytetracycline in

Fig. 1. Rabbit platelets. Glutaraldehyde fixation, followed by osmium tetroxide. Kodak 'Dektol' development, with gold intensification. Developed silver grains lie primarily over platelets. Unstained. ( $\times 18,000$ )

the drinking water soon began to show an accelerated rate of weight gain, better development of hair and heightened physical activity. The differences between some littermates were noticeable at ten days. Afterwards, the animals receiving terramycin developed relatively normally, while cortisone-treated animals not receiving terramycin developed severe wasting disease and began to die between 20 and 30 days. About this time the thymectomized animals also began to show signs of retarded development (Fig. 1).

Animals dying with cortisone-induced wasting disease showed lymphoid hypoplasia, poor development of sub-

cutaneous fat and connective tissue, and collections of polymorphonuclear leukocytes in the lungs and bronchi, wall of the small bowel (Fig. 2) and hepatic portal tracts. Pair-killed littermates having terramycin in their drinking water showed lymphoid hypoplasia but no prominent infectious disease histologically. Development of connective tissues in animals of this group older than about 30 days also did not seem impaired compared to sham-thymectomized animals of similar age.

Schlesinger and Mark<sup>1</sup> suggest that the cortisone-induced wasting syndrome may result from metabolic disorders induced by the loss of thymic factors normally antagonistic to steroids. Glucocorticoids are known to inhibit mitosis<sup>2</sup> and Lehtiharju *et al.*<sup>3</sup> have shown that steroids may differentially inhibit DNA synthesis in mouse tissues. It seems possible that inhibition of development of the lymphoid tissues of the mouse by steroids might allow infectious agents to invade mouse tissues during the first weeks of life. The beneficial effect of oxytetracycline shown here suggests that infectious processes could contribute to the poor development and early death of the mice initiated by the neonatally administered steroids.

## Tissue Distribution of Zinc-65 in Tumour Tissue and Normal Tissue in Man

Zinc is a trace metal of physiological importance which is widely distributed in many enzyme systems. Changes in the activity of certain enzymes have been reported in normal and tumour tissues of tumour-bearing animals<sup>1</sup> and of man<sup>2</sup>, and in the serum of patients with neoplastic diseases<sup>3-7</sup>. Since the activity of some enzymes depends on the presence of specific trace metals, cellular derangement resulting in neoplasia may be linked with changes in trace metal concentration. Differences in zinc concentration in normal and tumour tissue in experimental animals and in man have been previously reported<sup>8-11</sup>.

In the work recorded here on man the uptake of zinc-65 in tumour tissue localized at different sites in the body was determined and was compared with that of the corresponding normal tissues. Samples of tumour tissue and of adjacent normal tissue were obtained at autopsy from nine patients with advanced neoplastic disease at time-intervals ranging from 1 to 71 days after the injection of a single intravenous dose of zinc-65 chloride of high specific activity. The age, the diagnoses of the patients and the type and localization of the different tumours in the body are listed in Table 1. The samples of tumour tissue obtained from patients 2, 3 and 6 were primary tumours, while the 11 samples of tumour tissue obtained from the remaining six patients represented metastatic tumour. The samples of normal tissue and of tumour tissue were wet weighed and 1-g aliquots were radioassayed in a well-type sodium iodide crystal  $\gamma$ -scintillation counter equipped with a single channel pulse height analyser at the zinc-65 peak<sup>12</sup>.

Tumour tissue localized in the liver concentrated considerably less zinc-65 than liver tissue uninvolved by tumour (Table 2), the ratio of zinc-65 concentration in

† Primary tumours; all other samples of tumour tissue were secondary tumours.

normal tissue as compared with that of tumour tissue ranging from 3:1 to 28:1. The zinc-65 uptake in both tumour tissue in liver and in liver tissue uninvolved by tumour was lower per gram in patient 3, who had a primary tumour of the liver, than in patient 4, who had metastases in the liver. The tissue samples of both these patients were obtained at comparable time intervals after the injection of zinc-65 (11 days). Despite these differences in zinc-65 concentration in normal liver tissue and in tumour tissue of these two patients, the uptake ratio of normal/tumour tissue was similar in patient 3, who had a primary tumour (hepatoma), and in patient 4, who had metastatic liver disease.

Tumour tissue located in organs other than the liver, for example, in the lung, spleen, lymphnodes, ovary and pancreas, had a similar or a somewhat greater uptake of zinc-65 than the corresponding normal tissues. Two of the samples of tumour tissue in the lung were primary tumours (patients 2 and 6, Table 2). The zinc-65 uptake in one of these tumours (patient 2) was 5 times higher than that of lung tissue uninvolved by tumour, while the zinc-65 uptake in the primary tumour of the lung in patient 6 was similar to the uptake in the metastatic lung tumours. The radioactivity in lymphomatous tissue localized in psoas muscle was twice as high as that of the muscle tissue not involved by tumour.

The high uptake of zinc-65 in normal liver tissue in man<sup>17</sup> may be due to a combination of factors, such as rich vascularization of this organ, the presence of zinc metallo-enzymes<sup>18</sup> and the binding of zinc to proteins<sup>19</sup>. The lower zinc-65 concentration in tumour tissue localized in the liver in man may be due to several factors such as deficiency of zinc containing enzymes in the neoplastic tissue, decreased vascularization and changes in protein content in tumour tissue. The low zinc-65 uptake in tumour tissue localized in the liver is in agreement with data on stable zinc concentration in man reported by

Olson<sup>11</sup>. Low levels of zinc have been reported in cirrhosis of the liver and in other hepatic dysfunctions<sup>20</sup>.

The concentration of zinc is high in prostatic tissue in man. However, the concentration of zinc in tumour tissue localized in the prostate gland is approximately one-third that of the normal prostate<sup>14</sup>. A report on the zinc content in three different types of tumour localized in the thyroid gland in man indicates that the zinc concentration may depend on the cytological type of the tumour<sup>13</sup>. In the latter investigations, the concentration of zinc was higher in a sample of reticulum cell sarcoma in the thyroid gland and in a sample of papillary carcinoma than in normal thyroid tissue while the zinc concentration was lower in recurrent thyroid carcinoma and in necrotic thyroid adenoma than in normal thyroid tissue. In some animal investigations, the zinc-65 uptake has been reported to be higher in tumour tissue as compared with non-malignant tissue in tumour-bearing mice<sup>8,10</sup>.

The results presented here and the reports in the literature indicate that tumour tissue which is located in organs that normally have a low concentration of zinc have a similar or a greater zinc-65 uptake than the tissue in which the tumour is located. On the other hand, tumour tissue located in organs which normally have a high zinc concentration, for example, the liver and the prostate gland, have a lower zinc-65 uptake than liver and prostatic tissue uninvolved by tumour. The zinc content of white blood cells has also been reported to be high<sup>13</sup>, while the zinc content in leukaemic leucocytes has been found to be decreased<sup>4</sup>. Recently, a decrease in the zinc content has been observed in leucocytes of patients with a variety of neoplastic diseases and this difference has been suggested as a test for the diagnosis of cancer<sup>21</sup>. In tissues in which zinc seems to have a special metabolic function, deficiency of this trace metal may lead to alterations in cellular function and structure and ultimately result in neoplasia.

## RADIOBIOLOGY

## Migration of Spleen Cells into the Blood Stream following Antigen Stimulation of the Rat

A MARKED cellular hyperplasia occurs in the rat spleen in response to a single intravenous injection of a particulate antigen<sup>1-3</sup>. This hyperplasia is predominantly manifested in the red pulp, which exhibits a striking increase in the number of actively mitotic, large pyroninophilic cells within 2 days after antigen administration. The proliferation of these cells, which have been shown to be intimately associated with antibody formation in the rat<sup>4,5</sup> as well as in other species<sup>6</sup>, reaches a maximum on about the fourth day after antigen. Later, their number rapidly diminishes so that by the ninth day the spleen has largely regained its pre-stimulation pattern and few if any of these cells appear to differentiate locally into plasma cells.

The fate of these 'antibody-forming cells' has not been established with certainty, although there is morphological evidence suggesting direct migration into the blood stream<sup>7</sup>. At about the time of maximal hyperplasia, cells resembling small lymphocytes make a transient appearance in the red pulp. It has been suggested that the antibody-forming cells shed their cytoplasm and give rise to these small lymphocytes which then migrate from the spleen<sup>8,9</sup>. This interpretation was strengthened when lymphocytes exhibiting specific adherence of the bacteria used for immunization were demonstrated in the blood<sup>8</sup>. However, immune adherence gives only indirect evidence in support of the proposed cellular migration, particularly since the possibility of cellular contributions from extra-splenic sources was not excluded.

In the present experiment, cell migrations into the blood stream of the rat were investigated by using tritiated thymidine to label the proliferating pyroninophilic or 'antibody-forming' cells of the spleen. For selective labelling of the spleen cells, the spleens were first exteriorized with intact vascular pedicle and protected in a lead shield while the remainder of the body was subjected to X-irradiation, a technique described by others<sup>8</sup>. A dose of 900 r. was necessary to suppress adequately the incorporation of tritiated thymidine into the actively mitotic extrasplenic tissues such as gastro-intestinal tract, bone marrow and lymph nodes. Eighteen hours after X-irradiation, which is within the period of maximal lymphocytic suppressive effect of the irradiation, tritium thymidine (specific activity 0.36 c./mmole) was injected intraperitoneally at a dose of 25  $\mu$ c./100 g. Six hours after tritiated thymidine injection the animals were killed. Samples of spleen and blood buffy coat smears were fixed in Carnoy's fixative. The smears and spleen sections were covered with stripping film (Kodak 'AR 10') according to the method of Pelo<sup>10</sup>. Autoradiographs were stained with methyl green-pyronin after 25-30 days' exposure.

Twelve young male rats (Sprague-Dawley) were assigned to 4 experimental groups. The first group was injected intravenously with 1.0 ml. of a standard formalinized typhoid vaccine. Three days later the rats were irradiated with spleen-shielding. They were killed on the following day, 6 h after receiving tritiated thymidine. The second group was similarly treated except that physiological saline was substituted for typhoid vaccine. In the third group, which also received antigen, irradiation was performed without spleen-shielding. The fourth group, a control for the splenic histology, received antigen but not irradiation or tritiated thymidine.

The spleens of the antigenically stimulated rats which were irradiated with spleen-shielding exhibited a histological pattern qualitatively similar to that of the unirradiated controls. The only prominent difference was a decreased number of lymphocytes in the white pulp. The greatly hyperplastic red pulp contained many labelled cells in-

cluding most of the large pyroninophilic cells and the clusters of smaller cells resembling lymphocytes (Fig. 1). The large cells of the germinal centres also showed appreciable labelling, but the smaller lymphocytes of the white pulp were not labelled. The histological pattern in the saline-injected rats which were irradiated with spleen-shielding was essentially normal except for a decrease in the number of white pulp lymphocytes. The relatively small number of labelled cells included a few scattered large pyroninophilic cells in the red pulp and some of the large cells of the germinal centres. The spleens of the antigenically stimulated rats subjected to total-body irradiation without spleen-shielding were severely atrophic. Only rare cells, chiefly fibroblasts and histiocytes, were labelled.

In investigating the labelling of blood cells, lymphoid cells were classified so far as possible on the basis of morphological criteria used by others<sup>10,11</sup>. Cells were assigned to 3 categories: (1) small lymphocytes; (2) medium lymphocytes and large pyroninophilic cells; (3) unclassified cells including blast cells and 'basket cells'. Polymorphonuclear leukocytes, none of which was labelled, were excluded. In all, 2,000 lymphoid cells, 1,000 from each of two slides, were counted from each animal. Labelled cells from the blood of antigen-stimulated, spleen-shielded animals are shown in Fig. 2. A marked lymphocytopenia was observed in the rats subjected to total-body irradiation without spleen-shielding: labelled cells were not present in the blood of this group. The labelled cells in the blood of the two spleen-shielded irradiated groups are enumerated in Table 1. The two groups were compared with respect to the total number of labelled cells per 2,000 lymphoid cells using Student's *t*-test with four degrees of freedom. A significantly greater ( $P < 0.005$ ) percentage of labelled cells was present in the antigenically stimulated group.

Fig. 1. The labelling pattern of the splenic red pulp on the fourth day after antigen. Numerous large pyroninophilic cells clustered about an arteriole are heavily labelled, as are the small lymphocytic cells situated more peripherally. (Methyl green-pyronin,  $\times$  c. 670)

water. They are more acidic than the phenylcarbamate esters or the benzenesulphonamides, neutral, water-soluble, alkali metal salts being formed on treatment with the corresponding aqueous bicarbonate solution. The potassium salts have been extensively used in field trials. Estimation of residues in plant materials can be effected by the classical procedures in present use for estimation of sulphonamides, based on the presence of a diazotizable aromatic amine group. Both M and B 8882 and M and B 9057 are readily converted into sulphanilamide. Toxicity in experimental animals is low; acute oral  $LD_{50}$ 's in mice, rats, rabbits and hens range from 1,000–5,000 mg/kg.

M and B 8882, M and B 9057 and M and B 9555 kill some graminaceous species, including wild oats and some grass weeds, while M and B 8882 and M and B 9057 also kill dicotyledonous species. Levels of herbicidal activity, determined by pre- and post-emergence application using established methods<sup>6</sup> under greenhouse conditions, are set out in Tables 2 and 3. Tolerant crop species include linseed (flax), lucerne, potatoes, black currants, raspberries, sugar cane, oil poppy, and some crop grasses. The growth of cereals is affected at herbicidal rates.

The new herbicides are absorbed by the leaves and the roots of susceptible species at seedling and later stages of growth, unlike protham and chlortham, which are absorbed only by roots. The effects of foliar application develop slowly and are very characteristic. After two weeks, susceptible plants become chlorotic and lose vigour, then the growing points cease to grow, and after 5–6 weeks the plants die or are so seriously arrested that they offer little, if any, competition to tolerant plants. The chlorotic and inhibitory effects appear in apical and axial meristems remote from treated leaves, being especially well marked in the tillers of *Avena fatua*, the buds of rhizomes of *Agropyron repens*, and the apex of *Rumex* spp., following application of M and B 9057 or M and B 8882.

The following experimental observations suggest that the herbicides act by interfering with cell division and expansion; the inhibitory action on meristems (already described here); seeds soaked in lethal concentrations

produce swollen and stunted roots; young dicotyledonous plants sprayed with M and B 9057 develop a larger number of smaller leaves. The phenylcarbamates cause similar inhibitory<sup>7,8</sup> and morphological effects<sup>9</sup> when taken up by the roots of plants, and so does barban when applied to leaves of wheat and wild oats<sup>11</sup>. Although chlorosis is the most obvious symptom it is less intense than that caused by amitrole and therefore possibly of lesser importance in killing plants. Unlike the phenylcarbamates, none of these compounds inhibits the Hill reaction at concentrations of up to  $10^{-3}$  molar<sup>12</sup>.

Field trials in Great Britain, Canada<sup>13</sup> and the West Indies show that the three herbicides are of interest for controlling grass weeds, by both pre- and post-emergence application. Two of them, M and B 8882 and M and B 9057, are of interest also for killing composite, cruciferous and polygonaceous weeds. The situations in which they would be of practical value have not been fully explored, but the removal of grass weeds in certain grass crops appears to be possible. Practical rates of application have, in some instances, been reduced by the addition of a wetting agent to the spray solutions. An account of the chemical and biological properties of these sulphonylcarbamates will be published elsewhere.

## Non-essential Role of the Adrenal Medulla in the Hibernation of the 13-Lined Ground Squirrel

ALTHOUGH the adrenal cortical hormones are reported to be necessary for successful hibernation and arousal in European ground squirrels, *Citellus citellus*<sup>1</sup>, and in European hamsters, *Cricetus cricetus*<sup>2</sup>, the necessity and function of the adrenal medullary hormones are still in doubt. Most investigators agree, however, that these catecholamines, especially norepinephrine, are probably involved in chemical heat production by torpid and arousing hibernators<sup>3–5</sup>. Although totally adrenalectomized hibernating animals arouse in a nearly normal manner, a return to normal hibernating patterns is prevented unless adrenal cortical tissue is transplanted into the anterior chamber of the eye or unless cortisone or deoxycorticosterone acetate (DOA) is administered<sup>1,2</sup>. Presumably, then, the hormones of the adrenal medulla are not needed for at least short 'bout' of hibernation or for arousal, even though the importance of the sympathetic-adrenal system in spontaneous arousal has been repeatedly emphasized<sup>4,6–8</sup>.

The work recorded here was initiated to obtain more information on the influence of the adrenal medullary hormones in hibernation and arousal during an entire hibernating season.

Six male 13-lined ground squirrels (*O. tridecemlineatus*) were bilaterally adrenalectomized in July, but a remnant of adrenal cortical tissue was left *in situ*. Cortical regeneration occurred during the following seven weeks. Six control males were laparotomized, their adrenal glands being manipulated and slightly traumatized but not removed. On September 1 the animals were placed, one to a cage, in a cold room at  $6 \pm 0.5^\circ \text{C}$  with 2 h of light a day. The animals had food and water at their disposal at all times and were inspected each morning, five days per week, until the following May. Hibernation or arousal was recorded for each animal. While it is recognized that these animals may arouse from, and return to, a hibernating state within a 24-h period, nevertheless we believe that comparisons between the two groups are valid because any error would be common to all animals. The animals were autopsied at the termination of the investigation, the remnants of adrenal cortical tissue being examined histologically for any evidence of medullary tissue. None was found in any of the animals.

A total of more than 1,000 animal days (No. of animals  $\times$  No. of days of observation) was recorded for each group. For convenience and compilation purposes, the 9 months of observations were divided into 15-day periods, beginning September 1. The percentage of animal days spent in hibernation during each period was calculated and plotted (Fig. 1). Each 15-day period comprises approximately 55–72 animal days.

The medullectomized animals hibernated for 75.4 per cent of the entire period, while the controls hibernated for 86.3 per cent of the time. The difference between the two groups with respect to the proportion of time spent in hibernation was limited to the first six weeks. After this initial period, however, no significant differences could be seen between the groups in either percentage of time in hibernation or duration of bouts of hibernation. We conclude, therefore, that medullectomy disrupted the normal processes preparatory to hibernation and thereby delayed its onset. During January, sharp decreases in the amount of time spent in hibernation occurred in both groups and continued through the rest of the experimental period.

One medullectomized animal remained fully awake, and presumably homeothermic, after February 4. Another of these animals aroused permanently on March 18. Two of the remaining four were found dead on April 5; the other two died on May 7. In the control group, three animals were terminally aroused by April 12, one was fully aroused by May 22 and the other two hibernated sporadically through May and even into June.

The results of this investigation indicate that animals lacking the adrenal medullary catecholamines enter into,

and arouse from, hibernation in a normal manner, although the initial entry into hibernation is somewhat delayed in the medullectomized animals. Both the medullectomized and the control animals show the typical hibernation pattern, in which the duration of a 'bout' of hibernation and the percentage of time in hibernation are maximal in mid-winter<sup>10</sup>. We may assume, therefore, that the catecholamines of adrenal medullary origin are not required for successful hibernation or arousal. The concentration of catecholamines in adrenal medullary tissue is reportedly reduced or variable during hibernation<sup>11–13</sup>. Most of these investigators relate the changes found during hibernation to the frequency of arousal. In contradiction to the findings recorded by the authors just cited, Suomala and Uusipää<sup>14</sup> reported that the concentration of epinephrine within the adrenal medulla of the hedgehog increased during hibernation but decreased sharply immediately after arousal in the spring; Petrovic and Davidovic<sup>15</sup> noted a rise in the concentration of catecholamines within the adrenal medulla at the end of hibernation with a marked decrease in this concentration on terminal arousal. These and our results suggest that, at the time of spring arousal, the adrenal catecholamines may assume a special importance to the physiological well-being of hibernating animals. This may explain why four of six medullectomized animals died during the late stages of this experiment, while only one of the controls did so. Further experimentation on the importance of these compounds, particularly at the time of spring arousal, is needed.

## Secondary Walls in Phloem of *Pinus radiata* D. Don

Abbe and Crafts<sup>1</sup> showed that the development of secondary walls in the sieve cells of gymnosperms is apparently restricted to the Abietineae; there is no evidence of secondary wall in the sieve cells of Taxodineae, Araucarineae, Cupressineae and Taxineae. Moreover, the Abietineae develop no fibres, but the secondary walls of their sieve cells appear to be composed of relatively pure cellulose. Secondary walls occur in the sieve cells of white pine, *Pinus strobus* L. (Figs. 3 and 24 in ref. 1).

Barghoorn and Scott<sup>2</sup> examined the tracheids in thin sections of fossil material of *Pinus strobus* L. (Figs. 11 and 14) and *Sequoia* sp. (Fig. 16). They pointed out that the primary wall and the *S*<sub>1</sub> layer of the secondary wall are more resistant to degradative processes than the *S*<sub>2</sub> and *S*<sub>3</sub> layers of the secondary wall. In most of their pictures

Fig. 1. Transverse section of phloem photographed in ordinary light. Note the intact primary walls (b) for two contiguous cells. ( $\times 1,200$ )

Fig. 2. Same as Fig. 1, seen between crossed nicols. The primary walls (b) are weakly birefringent; the collapsed material (c), because of the great birefringence, is interpreted as the secondary wall. ( $\times 1,200$ )

$S_2$  and  $S_3$  layers have collapsed away from  $S_1$  and the primary wall, leaving a gap.

In the present work cambial strips with a thick layer of phloem, preserved in formalin-acetic acid-water (10:5:85), were embedded in wax and sectioned at  $20\mu$ . The sections were placed in 25 per cent alcoholic hydrochloric acid for 2 h, washed with water and placed in 0.5 per cent ammonium oxalate for 15 min. Staining was done by Foster's ferric chloride-tannic acid method<sup>2</sup>.

Fig. 1 shows two adjacent sieve cells photographed in ordinary light. Collapsed material is present in each cell. Fig. 2 shows the same two cells between crossed nicols. The collapsed material (c) and the bounding walls (b) of each cell are both birefringent, suggesting that both are cellulose-containing wall layers. The weak birefringence of the bounding layer and the strong birefringence of the collapsed layer suggest that most or all of the secondary wall layers have collapsed away from the primary wall.

These results support Barghoorn and Scott's claim that secondary walls are less resistant to degradation than primary walls.

I thank Dr. I. V. Newman for his advice.

### Influence of Compensatory Mechanisms and the Pineal Gland on Dark-Induced Gonadal Atrophy in Male Hamsters

It has been postulated that the gonads of male and female hamsters regress to a non-functional state as a normal seasonal response to short days and low temperatures in the autumn and winter<sup>1</sup>. Under laboratory conditions, the same results follow exposures to short photo-periods<sup>1-3</sup>. The functional change in the gonads is evidently controlled by the pineal gland, which itself responds to changing light periods, since pinealectomized animals show no regression of gonads when they are exposed to short photoperiods. A variable hypertrophic response of one gonad is a result of excision of the other. There are, therefore, probable hormonal processes which exert effects on the gonads opposite to those exerted by the pineal gland. In the course of our work, there arose a question as to whether the depressant action of the pineal gland could be counteracted by the compensatory processes which follows unilateral castration. The following experiments were designed to elicit an answer to this question.

Thirty-eight male hamsters were pinealectomized or subjected to a sham operation by techniques established in this laboratory<sup>4</sup>. In addition, all animals were unilaterally castrated by standard techniques and the excised testes were weighed to the nearest mg. Half of each group was exposed to daily light:dark (LD) cycles of 1:23 and the other half was maintained on LD cycles of 16:8. All animals received a standard rodent diet and water *ad libitum*. After four weeks the animals were killed and the weights of the remaining testes were obtained. The data were subjected to a two-factor analysis of variance and the means and standard errors of the means (S.E.M.) were calculated. The data were tested for significance ( $P < 0.05$ ) by use of Student's *t* test.

Previous experiments have demonstrated conclusively that four weeks of exposure to short daily periods of light are sufficient to produce atrophy of the male hamster gonad<sup>1,2</sup>. In the present experiment, however, it will be noted (Table 1) that the remaining testes of sham-operated animals in LD 1:23 regressed only slightly (not significant). The remaining gonads of the other 3 groups maintained or increased their weight as had been expected.

To ascertain whether dark-induced gonad atrophy could be reversed by pinealectomy or by compensatory mechanisms, animals which had been in LD 1:23 cycles for four weeks were unilaterally castrated and the weights of the excised testes were recorded. Half the animals were then pinealectomized and the other half were subjected to a sham operation and all animals were returned to LD cycles of 1:23. Four weeks later, these animals were killed and the remaining testes were weighed and compared with the weights of the previously removed testes.

Because the cranial surgery and unilateral castration were done at the same time, we could not divide the animals into pinealectomized and sham-pinealectomized groups having similar mean weights of the removed testes. Consequently, the initial mean weights of the testes in the two groups were significantly different (Table 2;  $P < 0.01$ ). This variable response at four weeks has been previously documented<sup>1</sup>. Because of this and because the response of the remaining testes was variable in the sham-pinealectomized group, the data for each individual are

tabulated in Table 2 along with the means and standard deviations.

After pinealectomy (A, Table 2), the mean weight of the remaining testes increased significantly (three-fold) during the following four-week period, lending additional confirmation of the inhibitory role of the pineal gland on gonad functions. On the other hand, the mean weight of the remaining testes of the sham-operated animals was unchanged, or decreased slightly. While the remaining gonads of all pinealectomized animals increased markedly in weight, those of only three of the sham-operated animals increased while two showed significant decreases and the remaining two showed no change (B, Table 2).

The results recorded in Table 1 show that those processes which are set in motion to compensate for partial loss of testicular tissues can be superimposed on the actions of the pineal gland to prevent its primary inhibitory effects. In this case, the initially enlarged, functional testis did not regress in the sham-pinealectomized, unilaterally castrated animals even though the pineal gland is presumably functional (inhibitory) in short light cycles. However, testes already atrophied or affected by exposure to short photo-periods fail to respond or respond variably to compensating processes in the presence of a functional pineal gland (Table 2). In its absence, however, marked enlargement of the remaining testis can occur. We infer from these data that if normal functional testes are present, normal pituitary-gonad hormonal balance exists. Consequently, compensating mechanisms are called into play when one testis is removed. Such mechanisms appear to be adequate to prevent any gonad-inhibitory actions by the pineal gland. On the other hand, already atrophied or dark-affected gonads imply modified pituitary-gonad hormonal interrelationships. In this case, removal of one testis may or may not stimulate compensating mechanisms. Only when the pineal gland is removed can gonad recrudescence become consistently possible under these conditions.

Our results demonstrate that in reproductively functional male hamsters, compensatory mechanisms can offset the effects of an active pineal gland. Further, we have made observations (unpublished) which suggest that the inhibitory effects of short daily periods of light on male gonads can be considerably modified (reduced) when two or more animals are in the same cage or if a normal female is in the same cage with the males. Thus, social contact, olfactory stimuli, or hormonal compensating mechanisms all appear to potentially interfere with or modify the primary inhibitory effects of an active pineal gland in short photo-periods.

We may tentatively look on the pineal gland as an organ which is called into play when the environmental photo-periods dictate a reduction in reproductive func-

tions. However, other stimuli may apparently be superimposed on and reverse these actions under appropriate conditions so that survival and perpetuation of the species are ensured. The pineal gland appears to be only one of a spectrum of exteroceptive factors regulating reproductive cycles in a changing external environment.

### Incidence and Lobar Distribution of Bronchiectasis in a Colony of Wistar Albino Rats

In some recent dietary investigations using a closed colony of Wistar albino rats the most common pathological condition was an inflammatory and suppurative disease of the lungs. This disease, a form of bronchiectasis, occurs frequently as a natural disease in rats, both domesticated and wild<sup>1</sup>, and has previously been described<sup>2</sup>. In extent it varies from a small focus of inflammation in one lobe of the lung to the entire lung being shrunken and nodular, the tissue of each lobe being converted into large sacs consisting of distended bronchi filled with a compacted caseous mass. Nelson and Gowen<sup>1</sup> have reported the incidence of the disease in male and female rats but only from a total of 145 animals. Other reports give the percentage incidence for the entire colony regardless of age and sex<sup>3,4</sup>. In the work recorded here 1,238 rats were examined and as no dietary differences were found<sup>4</sup> the opportunity was taken to sum over diet to obtain a detailed picture of the incidence of this natural disease in the colony. Particulars of the maintenance of the colony are given by Hickman *et al.*<sup>5</sup>.

At post-mortem examination a note was made of the number of each sex exhibiting pulmonary disease and also the number and position of the lobes affected. The results were then divided into six six-monthly age groups (Fig. 1). Of the 621 males and 617 female rats examined, 418 males

Fig. 1. Black, bronchiectasis in all 5 lobes of lungs; double hatched, 3-4 lobes affected; vertically hatched, 1-2 lobes affected; white, lungs inflated

and 406 females showed pathological changes in the lungs. Fig. 1 shows that only 4-9 per cent of the rats exhibited pathological changes in the first six months of life, and, of the 75 examined, only one animal under 2 months of age (a male of 50 days) showed any inflammation. By 2-4 months, however, the incidence rose to 10 per cent in the males and 3 per cent in the females. This difference in susceptibility between the sexes was maintained in the 6-12 months age group (males 58 per cent; females 42 per cent). Application of a  $\chi^2$  test to the summed results for the period 0-12 months (males: 60 diseased animals out of 221; females: 31 diseased animals out of 198) showed that the difference is statistically significant ( $P < 1$  per cent). Thus the male would appear to be more susceptible to pulmonary disease than the female during the first twelve months of life. By the time the animals were 12-18 months old there was very little difference in the incidence of the disease between the sexes (male: 85 per cent; female: 82 per cent), and at 18-24 months no difference at all (both 94 per cent). Viewed overall it is seen that animals are first contracting the disease up to an age of 18 months. After this period, when the incidence of lung pathology has risen to 91-94 per cent, the animals still unaffected (6-9 per cent) appear to remain immune (the column for females 30-36 months old provides the only exception, but since this is based on the data from only 24 animals, one of which provides 4 per cent of the total incidence, the value of the exception is doubtful). Although it appears that no more animals contract the disease after 18 months, the severity of the disease in each affected animal increases with time.

Bronchiectasis in rats has been attributed to a viral infection<sup>1,2</sup>. Cruickshank<sup>3</sup> believes that the disease is initiated by bronchial obstructions caused by the swelling of the mucosal lymphoid tissue. Mucus accumulating distally to the obstruction would then plug the bronchus and cause an inflammatory reaction, the combination of obstruction and sepsis eventually leading to bronchiectasis. He notes that the virus isolated by Nelson may well be the cause of the initial enlargement of the bronchial lymphoid tissue. In this connexion it is of interest to note that in the present experiment the occurrence of enlarged lymph nodes (0-18 months: males 3 per cent, females 1 per cent; 18-36 months: males 16 per cent, females 8 per cent) was significantly higher in males than in females ( $P < 1$  per cent in 18-36 months' age group); this clearly supports Cruickshank's theory. It is possible that the increased incidence of bronchiectasis in males, also noted by Nelson and Gowen<sup>1</sup> (although their results were insufficient for analysis), may be due, at least in part, to the usual methods of colony maintenance. In the present colony the animals were maintained at 3 to a cage except after mating when the females were placed in individual cages to produce their litters. The females were mated when 12-13 weeks old and on average spent five weeks in isolation, except for the presence of their litters, just at the age when animals were beginning to be found having the disease. If the initiation of bronchiectasis is due to an airborne virus the separation of the females into individual cages may reduce their chances of contracting the disease to an extent sufficient to cause a significant difference between the sexes in a time-incidence graph.

It is clear from an examination of the lobar distribution of the disease that the initial stages of bronchiectasis are not uniformly distributed throughout the lung (Table 1). The right superior lobe is scarcely ever affected by the initial stages of the disease whereas the median or post-caval lobe is affected more than three times as often. Examination of 25 healthy animals showed that the distribution of the weight between the lobes was: right superior 13 per cent, right middle 13 per cent, right inferior 19 per cent, right median or post-caval 11 per cent and left lung 35 per cent; there appeared to be no variation in percentage distribution with age. Thus the two lobes most frequently affected, the basal lobes (right inferior and median), are

Table 1. LOBAR DISTRIBUTION OF BRONCHIECTASIS IN THE LUNGS OF RATS WHEN ONE, TWO, OR UP TO FOUR LOBES ARE AFFECTED

No. of lobes affected	Location of infection					Total No. of lobes affected	No. of animals involved
	Right superior	Right middle	Right inferior	Median	Left		
<b>Males</b>							
1 lobe	1	7	9	9	11	37	37
2 lobes	4	15	19	25	17	80	40
Totals	5	22	28	34	28	117	77
<b>Females</b>							
1 lobe	2	13	8	13	17	53	53
2 lobes	11	17	19	19	8	74	37
Totals	13	30	27	31	25	126	89
<b>Combined sexes</b>							
1-2 lobes	18	53	55	55	53	243	166
1-4 lobes	80	149	152	156	133	670	295

both smaller than the less frequently affected left lung. Weight for weight the tissue of the median lobe is four times more susceptible to bronchiectasis than is that of the left lung. The variation in the incidence of disease between the lobes of the lung is not due to differences in lobe size and thus a higher probability of contraction of disease. It may possibly be attributed to the drainage of mucus into the basal lobes, which, if obstructed, would be the first to be occluded. The distribution of the disease from lobe to lobe may not be caused by the movement of infected material, but simply be due to the varying rates at which damage first becomes apparent in lobes initially affected to an almost equal extent.

## ENTOMOLOGY

### DDT-metabolism in Resistant and Susceptible Stable-flies and in Bacteria

THE main cause of resistance to DDT in insects is an increased rate of detoxication, although other mechanisms (such as higher lipid content, or lower nerve sheath permeability) have been suggested<sup>1</sup>. Products of DDT-metabolism in insects are DDE, kalthan, and water soluble conjugates<sup>1</sup>, while yeast<sup>2</sup> and rat liver<sup>3</sup> metabolize DDT to TDE.

The following experiments were performed to investigate whether absorption, metabolism, or excretion of DDT may be a cause of resistance in the stable-fly (*Stomoxys calcitrans* (L.)). Strains of stable-flies developed resistance to DDT (30 times), methoxychlor (110 times) and TDE (extremely high level) when kept under selection pressure of DDT in the laboratory. The resistance to the three insecticides was mainly due to one gene allele<sup>4</sup>.

Fig. 1. Absorption and excretion of topically applied <sup>14</sup>C-DDT. The points represent the radioactivity per fly and are based on the average of 10 flies. The activity of the external tissues is added to the internal activity before plotting: 0, susceptible flies; +, resistant flies; 1, Internal + external activity; 2, Internal activity.

Fig. 2. The radioactivity on chromatograms developed in:  $\beta$ -methoxy propionitrile (stationary phase); isooctane (mobile phase). Carrier substances (10  $\mu$ g of TDE, DDT and DDE) were detected by the method of Mitchell<sup>7</sup>. The solvent front was invisible. The flies were kept 24 h after treatment with  $^{14}$ C-DDT before they, and the excrement, were extracted and chromatographed. A, resistant flies; B, susceptible flies; C, excrement of resistant flies

Resistant and susceptible flies were treated with 0.0164  $\mu$ g  $^{14}$ C-DDT in acetone by topical application and kept at 25° C in glass cages. Excrement was collected for the first 24 h after application and extracted with acetone. Fresh blood was supplied every day. At various intervals after the application, samples of 10 flies were removed, rinsed in petrol ether, ground in a mortar and extracted 3 times with acetone.

*Serratia marcescens*, *Alcaligenes faecalis*, and one unidentified bacterial strain were isolated from the excreta of flies kept in sterile cages. These isolated strains and laboratory strains of *Escherichia coli*, *Bacillus brevis* and *Aerobacter aerogenes* were grown in meat extract bouillon containing  $^{14}$ C-DDT under nitrogen atmosphere (anaerobically), in unshaken cultures (oxygen deficiency), and in fully aerated cultures at 25° C or 37° C. After 24 or 72 h sulphuric acid was added<sup>8</sup>. The radioactivity was completely extracted from the incubation mixtures with hexane. Radioactivity was determined in a 'Tracerlab' windowless flowcounter. Aliquots of external rinses and internal extracts were plated.

All extracts were purified by acetonitrile elution<sup>8</sup>, and subjected to paper chromatography on Whatman No. 1 paper. The solvent systems used were vaseline-ethanol-water-ammonia<sup>9</sup>, phenoxyethanol-isooctane<sup>9</sup>, soya bean oil-methanol-water<sup>1</sup>,  $\beta$ -methoxy propionitrile-isooctane<sup>9</sup>. Radioactivity in the chromatograms was located by cutting the paper into pieces 1  $\times$  2 cm and counting them individually.

Samples of resistant flies were also treated with 10  $\mu$ g TDE and killed after 10, 20 and 30 h. Similar extracts were subjected to paper chromatography in the same systems. The silver nitrate reagent<sup>7</sup> was used for the detection of spots.

There was no difference in the rate of absorption, detoxication or excretion of DDT by resistant and susceptible flies (Figs. 1, 2A and 2B). Both make only small amounts of DDE. TDE was the only substance detected on the chromatograms of extracts of TDE-treated flies.

In the excrement of  $^{14}$ C-DDT-treated flies, DDT, DDE, TDE and MI were found (Fig. 2C). MI was water soluble and could be hydrolysed by acid to give a substance less soluble in water.

When growing anaerobically or in oxygen deficiency, the facultative anaerobes *S. marcescens*, *E. coli*, and the unidentified strain, converted DDT almost completely to TDE (about 90 per cent) and DDE (5 per cent). In aerated cultures neither the facultative anaerobes nor the obligate aerobes converted any DDT to TDE or other products.

As there is no difference in the rate of absorption, metabolism and excretion by resistant and susceptible flies, the resistance mechanism must be of an unusual kind.

Bacteria from the intestines of the flies were able to convert DDT into two (DDE and TDE) of the three DDT-metabolites found in fly excrement. This further indicates that the cause of resistance to DDT, methoxychlor and TDE in stable-flies is not a detoxication mechanism, in spite of the high degree of resistance present.

## Human Sweat Components Attractive to Mosquitoes

WHETHER human sweat is attractive to mosquitoes is a controversial problem. Howlett<sup>1</sup>, Rudolfs<sup>2</sup> and Rahm<sup>3</sup> concluded that human sweat was not attractive; however, Parker<sup>4</sup> and Brown<sup>5,6</sup> found the contrary. Recently, Brown<sup>7,8</sup> reported that lysine and alanine are attractive to *Aedes aegypti* (L.).

We have investigated the attractiveness of human sweat in a dual-port olfactometer modified from the design of Willis<sup>9</sup>. A charcoal-filtered, humidified air-stream is split into two equal portions and passed through glass coils submerged in a constant temperature water bath, which heats the air-streams to 27° C. Air flow rate measured by two glass-float flowmeters is kept at 2 l./min. Two glass tubes 150 mm  $\times$  30 mm with inlet and exit connections following the flowmeter hold the samples. The tubes are 3/4 filled with glass beads 4 mm in diameter. Five ml. of the test sample is placed in one tube and 5 ml. of distilled water in the control tube. The air-streams after passing through the sample tubes connect directly to two Buchner funnels 5 cm in diameter and placed side by side which exhaust into the test cage measuring 12 cm across, 10 cm deep, and 6 cm high. The two open ends of the test cage are covered with 40 mesh nylon net.

Attractiveness or repellency was determined by distribution of 20 mosquitoes in front of either port of the test cage. To determine the distribution, counts were made each min for a 10-min period. Cause for any

biased distribution of mosquitoes was checked by running water vapour in both air-streams prior to each test.

Female *Aedes aegypti* var. *quenslandensis* (Theo.) were used. The mosquitoes were fed a 5 per cent sucrose solution up until the time of testing and were deprived of a blood meal. Test mosquitoes were 8-10 days old and reared in the presence of males.

Our laboratory has demonstrated repeatedly with the olfactometer that air passed over human whole-body sweat is more attractive to female *Aedes aegypti* than a control stream of air (Table 1). In addition, after lyophilization the human sweat retains its attractiveness to female *Aedes aegypti* and the water removed by lyophilization is not attractive. When concentrations of lyophilized sweat in distilled water are high ( $\approx 1:1$ ), there is slight repellency. This agrees with Brown's statement<sup>6</sup> that sweat attracts at low vapour concentration and repels at a high concentration.

On dialysis of human sweat through 'Visking' cellulose for 10 days at 0°C, the attractive component(s) were separated into the dialysable fraction. In a typical dialysis using 100 ml. of sweat and  $2 \times 1,000$  ml. of distilled water, the weights of dialysable and non-dialysable fractions were 610 mg and 31 mg respectively. The non-dialysable fraction after lyophilization and redissolving in distilled water proved to be unattractive to female *Aedes aegypti* in the olfactometer.

Lyophilized human sweat was extracted with hexane, diethyl ether, acetone, isopropanol and ethanol; the extracts after removal of the solvent *in vacuo* were added to distilled water and evaluated in the olfactometer. The attractive component(s) were extracted only by diethyl ether and ethanol. The insolubility of amino-acids in diethyl ether would eliminate them as the attractive factor extracted. The residues left after exhaustive extraction at room temperature with diethyl ether followed by absolute ethanol were not attractive to female *Aedes aegypti*. Residues from the pure solvents used for extraction were found not to attract mosquitoes in the olfactometer.

Present efforts involve the use of thin-layer chromatography to separate and identify the attractive component(s) in human sweat. Table 2 shows the pattern obtained with chromatography of the ether and ethanol extracts of silica gel-G and kieselguhr thin-layer plates and gives some indication of the degree of complexity of the extracted materials.

It is somewhat surprising that the attractive component(s) present in human sweat are not volatile during lyophilization. However, in view of the low volatility of many of the sex attractants for insects we may assume that volatility in the usual chemical meaning is not of much importance in attracting insects.

Table 1. ATTRACTIVENESS OF HUMAN SWEAT FRACTIONS TO FEMALE *Aedes aegypti*

Sample	Identification	Concentration (wt./vol. water)	Olfactometer data.* No. of mosquitoes Control Sample port

## MICROBIOLOGY

### Growth of Mammalian Cells in a Heat-stable Dialysable Medium

NEARLY all media routinely used for cell culture contain from 5 to 40 per cent serum of a particular species of animal. As one might expect, there has been much research into the nature of the fraction or fractions of serum which form the active part of this material<sup>1-4</sup>. Despite this the exact nature of the activity of serum or its fractions is unknown.

A wide variety of macromolecular substances have been used, either alone or in combination with smaller than normal amounts of serum, in addition to a chemically defined base medium, in attempts to simplify tissue culture media. These include various peptones, lactalbumin hydrolysate, yeast extract, insulin, tryptic hydrolysate of milk and inert substances such as methylcellulose or polyvinylpyrrolidone.

A very limited number of completely chemically defined media exist which support the growth of mammalian cells *in vitro*<sup>5-14</sup>. The most successful of these media are those developed by Evans *et al.*<sup>8-11</sup>. The drawback of media of this type lies in their complexity, some containing as many as 70 components, the extended period of cell adaptation needed, the very limited spectrum of cells which the medium will support, or the constant replenishment of the cell monolayer which is necessary. In addition, the growth rate seldom matches that of the serum-containing parent line.

The present report deals with a simple, heat stable, dialysable medium which promotes the rapid growth of a mammalian cell line. Growth in two basic media of varying complexity is reported for comparison.

## Culture in London Study in Melbourne

An efficient method of transporting living cells and other specimens has become one of the biologists' most urgent needs. Now Union Carbide has developed a revolutionary new range of biological transporters embodying a unique principle of cryogenic storage which enables the temperature of the specimens to be kept below  $-130^{\circ}\text{C}$  for up to five days: long enough for a train journey across Europe or a freight flight from London to Australia. The new transporters consist of an aluminium outer shell with a plastics lining containing a porous specimen holder drilled to accommodate the

specimen ampoules. This holder is saturated with liquid nitrogen which gradually evaporates and is exhausted to atmosphere through pressure relief vents. The porous specimen holder eliminates the danger of spillage, and Super Insulation reduces the evaporation rate to 0.33 litres per day in the case of the BT-2 and 0.36 litres per day in the case of the larger capacity BT-3. Porous holders can be supplied to fit any shape of specimen container. Since the BT-2 holds 1.6 litres of nitrogen and the BT-3 2 litres, both transporters have a guaranteed static holding time of 5 days.

WCW 3318A

The basic cell line was originally isolated from adult normal rabbit myocardium. The original medium consisted of 10 per cent calf serum, 90 per cent Medium 199 (ref. 15), 50 units of penicillin and 50 µg streptomycin per ml. These cells were subsequently adapted to growth on the same medium in which the serum was replaced by 0.5 per cent autoclaved whole Difco 'Bacto-peptone' plus 100 mg per cent of glucose. These cells have undergone more than 270 passages and are passed every 6-7 days.

While attempting to simplify the added peptone fraction it was found that a dialysate of this fraction substituted quite well for the crude peptone material. This dialysate was prepared by dissolving 30 g of dry Difco 'Bacto-peptone' in 270 ml. triple-distilled water, and autoclaving it. 150 ml. sterile triple-distilled water was placed in 50-ml. quantities in 3 sterile dialysing tubes and placed directly into the peptone. Dialysis was carried out in the cold for 24 h with agitation. At the end of this time the material inside the bag was collected, and routinely gave a yield of 6-8 ml. per tube. The dialysate was placed in screw-capped tubes and autoclaved before use. Portions of each lot were lyophilized in a Virtis centrifugal 'Bio-Dryer' until dry, removed, weighed and reconstituted with sterile water. The average dry weight yield was 53 mg per ml.

**Media.** The 6 media compared were: 1, Medium 199, 90 per cent; calf serum, 10 per cent. 2, Medium 199, 99.5 per cent; crude autoclaved peptone, 0.5 per cent. 3, Medium 199, 99.5 per cent; autoclaved peptone dialysate, 0.5 per cent. 4, Totally autoclaved No. 3 above. 5, Eagle's minimum essential medium (MEM) without glutamine, 99.5 per cent; autoclaved peptone dialysate, 0.5 per cent. 6, Totally autoclaved No. 5 above.

No adaptation period was necessary when crude peptone cells were transferred to the dialysate medium. The cells were simply transferred and passed on the selected medium.

Growth curves were measured by inoculating 10-150-ml. 'Pyrex' milk dilution bottles with a given number of cells in a total volume of 10 ml. of medium. At 0 h, and every 24 h for a total of 7 days, one bottle was collected by use of a 1 per cent trypsin solution, and haemocytometer counts were made. All lines had undergone at least 10 passages in the individual media before they were used in the growth experiments. Many of these experiments have been repeated 10-12 times with essentially the same result.

Typical growth responses may be seen in Table 1. It is quite apparent that there is little if any difference in the growth rates of the cells in any of these media.

It is also quite obvious that macromolecules are not necessary to attain rapid growth. With regard to heat stability of the base medium, it is most logical to consider the simplest one, in this case Eagle's MEM. Here, one would expect the least stable substances to be pyridoxal and folic acid. Whether or not these substances are needed by this cell line is not known. Since the cells will not survive more than one passage on any of the base media alone, it is quite certain that the dialysate is essential for growth. Preliminary studies on the dialysate have indicated the presence of the free amino-acids threonine, serine, aspartic acid, glutamic acid, proline, glycine, alanine, hydroxylysine, valine, methionine, isoleucine, leucine, tyrosine, phenylalanine, lysine, histidine and

arginine, together with two unknown substances presumed to be peptides.

Preparation of media which contained added amounts of these free amino-acids in addition to either Medium 199 or Eagle's MEM medium did not result in cell growth. The addition of methylcellulose (0.12 per cent) to any of the base media used did not support cell growth.

The process of isolating, testing and identifying these 'peptides' is in progress. It is quite possible that obtaining these substances in a pure state, which will allow their incorporation in increased amounts without concomitantly increasing possible toxic substances, may allow for the production of a wide-spectrum, well-defined and stable medium for cell culture.

## Fractions of Staphylococcal Enterotoxin B

In a recent paper<sup>1</sup> we showed that enterotoxin B isolated from *Staphylococcus aureus* strain S8 could be separated into two main protein fractions by starch-gel electrophoresis. After the completion of this work we received communications concerning this observation from Dr. M. S. Bergdoll (University of Chicago) and from Dr. E. J. Schantz (U.S. Army Laboratories, Fort Detrick). Dr. Bergdoll told us that he has demonstrated the presence of at least 3 toxic fractions of enterotoxin B which would react with the same antibody<sup>2</sup> and suggested that denaturation during purification of the enterotoxin may be responsible for these fractions. Dr. Schantz informed us that he has obtained the two main protein components by starch-gel electrophoresis of purified enterotoxin. However, he was unable to resolve these by ultracentrifugation or by free electrophoresis; amino-acid analysis results were also consistent with a single molecular species of one polypeptide chain<sup>3</sup>. Dr. Schantz suggests, therefore, that the starch-gel fractions are artefacts produced in the gel by the current and possibly by the reaction of impurities with functional (charged) groups on the protein. Accordingly we have tried to resolve our fractions by methods other than starch-gel electrophoresis and we have re-examined the purification procedure to find whether the fractions appear as artefacts as a result of any stage of purification.

In order to test the suggestion by Dr. Bergdoll that the fractions were produced by denaturation during purification we re-cycled the toxin through 'Amberlite IRC 50' and ethanol-precipitation<sup>1</sup> and then prepared starch gels of the re-cycled toxin. We compared the relative opacity of the resulting bands with a control of untreated toxin

Table 1. GROWTH OF RABBIT HEART CELLS IN VARIOUS MEDIA

Medium	0	1	2	3	4	5	6	7
10% Calf serum + 199	2.8	3.3	5.0	8.3	11.3	12.4	14.0	14.6
0.5% Peptone + 199	1.8	2.2	3.2	7.4	12.5	14.1	15.2	16.4
0.5% Dialysate + 199	2.0	2.3	3.1	6.4	11.2	12.8	13.9	14.8
0.5% Dialysate + autoclaved 199	1.9	2.3	3.0	7.1	—	11.0	—	14.5
0.5% Dialysate + Eagle's MEM	2.1	2.2	3.8	7.2	—	10.4	—	14.0
0.5% Dialysate + autoclaved Eagle's MEM	2.1	2.0	3.0	6.6	10.6	11.9	14.1	14.4

\* All dialysate autoclaved 10 lb. x 10 min.

using a 'Chromosean' apparatus (Joyce, Loebel and Co., Gateshead). Since there was no difference we concluded that the purification steps did not affect the toxin. If starch-gel electrophoresis causes denaturation of enterotoxin B we would expect to see, after developing the gels, not discrete protein bands but a continuous streak of protein, representing the denaturation of more and more of the original species during the run. However, we have prepared 17 batches of the toxin and have always obtained two discrete main protein bands. Also, when unstained portions of these bands were cut out and re-run on starch gels they ran as single bands in their original relative positions; thus there was no evidence of inter-molecular transformations.

Since it is apparent that neither the purification procedure nor the separating technique is responsible for the appearance of the two bands, it remains to be discovered what the molecular difference is between the two bands and how this has arisen. Resolution on starch gel is dependent on protein size and charge. The two fractions were not separated by chromatography on 'Sephadex' G75, G100 or G200, in *tris*-citrate buffer at pH 8.88. This indicates, therefore, that they are of close molecular weight, and that separation by starch gel is not due to size difference and must thus be mainly dependent on charge. The two proteins, when extracted from starch gels using Gordon's cell<sup>4</sup>, were found to be serologically identical. Both proteins were precipitated at the same titre by an antiserum to one of them; serological identity was confirmed using Ouchterlony plates<sup>5</sup>.

The relative toxicity of the two fractions has been compared in pigs and young cats. We showed previously that starch-gel band 2 did not cause vomiting in pigs<sup>1</sup>. However, we find that both fractions cause vomiting when administered intraperitoneally to young cats, which are more sensitive to enterotoxin than pigs. However, the minimum vomiting dose of protein corresponding to band 2 was at least 3 times greater than that of band 1.

In conclusion, the two protein fractions are extremely similar and the only differences appear to be of charge and toxicity. We suggest, therefore, that the fractions that we have resolved on starch gels differ in secondary or tertiary protein configuration and that they do not appear to be artefacts of the purification procedure.

## VIROLOGY

### A Common Mode of Antiviral Action for Ammonium Ions and Various Amines

AMMONIUM ions and various aliphatic amines have been reported<sup>1-4</sup> to inhibit the growth of influenza virus in tissue culture. Recently, 1-adamantanamine was reported<sup>5</sup> to inhibit the multiplication of certain strains of influenza virus by slowing or blocking the penetration of virus into the host cells. In this communication we present results showing that ammonium ions and various aliphatic amines inhibit influenza virus growth by the same mechanism as 1-adamantanamine.

To demonstrate the nature of the action of the compounds, we have used the procedure of Davies *et al.*<sup>6</sup>. In this procedure, a virus inoculum in tissue culture systems is exposed to a compound for various periods of time. To some of the cultures, specific antiserum is added 15 min

before the end of each exposure period. The tissue sheets are then washed to remove the compound and the antiserum; fresh medium is added and the cultures are re-incubated. The amount of viral growth in the cultures treated with the compound indicates whether or not the compound has inactivated the virus or interfered with its adsorption to the host cells. Antiserum neutralizes extracellular virus, and the amount of viral growth in the cultures treated with the compound and antiserum indicates whether or not the compound has prevented penetration of the cells by the virus.

To produce optimal antiviral effect, ammonium chloride, the aliphatic amines and 1-adamantanamine must be added at the time of viral inoculation and must remain present during the entire incubation period. If the compounds are removed early in the incubation period, subsequent viral growth is not inhibited<sup>4-6</sup>. As shown in Fig. 1 (curve B), exposure of the viral inoculum to ammonium chloride for periods as long as 4 h did not result in inhibition of viral growth. This result indicates that ammonium chloride did not inactivate the virus on contact, and did not interfere with its adsorption to the host cells. Addition of antiserum to control cultures at the time of virus inoculation, or 15 min thereafter, greatly decreased subsequent viral growth. However, when the antiserum was added at 45 min or later, it had no effect on the viral growth (curve C). In contrast, addition of antiserum to tissue cultures containing ammonium chloride substantially reduced the viral growth, even when it was added as late as 3.75 h after virus inoculation (curve D). These results indicate that in the absence of ammonium chloride the virus was no longer susceptible to neutralization by antiserum 45 min after the virus was added to the tissue culture. In the presence of ammonium

Fig. 1. Effect of  $\text{NH}_4\text{Cl}$  and antiserum on an influenza A PB-8 virus inoculum as measured by its subsequent growth in monkey kidney tissue cultures. The cultures were inoculated with 0.1 ml. of a  $10^{-5}$  dilution of stock PB-8 virus,  $\text{TCID}_{50} = 10^{-4.5}$  ml.  $\text{NH}_4\text{Cl}$  (final conc. 250  $\mu\text{g}/\text{ml}$ ) was added 15 min before the virus (curves B and D). Antiserum (0.1 ml. of 1/5 dilution of serum) was added 15 min before the end of the indicated exposure period (curves C and D). The final vol. of the cultures was 2 ml., pH 7.2. At the end of each exposure period the tissue sheets were washed twice, fresh medium was added and incubation continued. The cultures were incubated at  $37^\circ\text{C}$  for 48 h, at which time haemagglutination titres were determined by Balk's procedure (ref. 6) adapted to use the microtitre technique (Cooke Engineering, Alexandria, Va.). Curve A, control; curve B,  $\text{NH}_4\text{Cl}$ ; curve C, antiserum; curve D,  $\text{NH}_4\text{Cl}$  + antiserum.

chloride, however, the virus remained susceptible to neutralization by the antiserum for as long as 3.75 h. Since ammonium chloride did not inactivate the virus, nor interfere with its adsorption to the cells, it must be concluded that the compound slowed or blocked the penetration of the cells by the virus. This effect on penetration is not complete. The small amount of viral growth in the tissue cultures treated with ammonium chloride and antiserum indicates that a small amount of virus had penetrated the cells in the presence of the compound.

Several amines, including propylamine, diethylamine, triethylamine, 1,3-diaminopropane HCl, 1,4-diaminobutane 2HCl and 1,5-diaminopentane 2HCl, were tested. At concentrations of 250 µg/ml. these compounds produced effects similar to those shown for ammonium chloride.

Ammonium chloride and the various aliphatic amines had no inhibitory effect against the Lee strain of influenza type B. In this respect, also, they were similar to 1-adamantanamine, which is inactive against strains of influenza B (ref. 5).

Since influenza virus neuraminidase may be involved in the infection process<sup>1</sup>, the effect of the various compounds on this enzyme was examined. PR-8 virus concentrated by high-speed centrifugation served as source of enzyme and malolactose (General Biochem. Inc., Chagrin Falls, Ohio) as substrate. Sialic acid released by enzyme action was determined by the Aminoff<sup>2</sup> procedure. Neither ammonium chloride, nor any of the other amines, tested at 1,000 µg/ml., affected neuraminidase activity.

Electron microscope studies suggest that intact influenza particles are taken into the cells by phagocytosis<sup>3</sup>. Our results show that ammonium chloride and various amines prevent this engulfment process. That this effect can be nullified by simply washing the cells suggests that the compounds may interfere with the penetration process by causing ionic changes at the cell surface. The failure of the agents to block a virus of influenza type B indicates that viruses of type A and B may penetrate the cells at different sites or differ in their tolerance of changes in ionic conditions. Of the various amines, only 1-adamantanamine shows antiviral activity in animals. This activity may be related to the fact that the compound reaches the site of infection in the body without undergoing changes.

### Growth of Foot and Mouth Disease Virus in Organ Cultures of Mouse Pancreas

THE use of organ culture techniques in the investigation of animal virus diseases allows the examination of the histo-pathological processes of infection to be made under conditions which resemble more nearly the *in vivo* state than the monolayer type of cell culture, but which permit a considerable degree of control of the organ or tissue environment. As yet, this kind of investigation has

not been widely made though observations have been reported on herpes simplex virus in skin<sup>1</sup> and also with polyoma and vesicular stomatitis viruses in mouse metanephric rudiments<sup>2</sup>. Preliminary work with foot-and-mouth disease virus (FMDV) has shown that in organ cultures of guinea-pig metatarsal pad<sup>3</sup>, virus multiplication will take place for up to four days, but only to a level at least 1,000-fold lower than in the metatarsal pads of the intact animal.

In adult *P* strain mice infected with unadapted FMDV the pancreas is the principal site of virus multiplication and a pancreatitis occurs<sup>4</sup>. In suckling mice, however, virus multiplication occurs mainly in the skeletal muscles and pancreatitis is absent<sup>5</sup>. The experiments reported here were undertaken to obtain more information about the susceptibility of the pancreas of the suckling mouse to this virus.

Pancreases to be cultured were removed aseptically from freshly killed 6-7-day-old *P* strain mice and placed in Eagle's basal medium containing 10 per cent calf serum. To initiate infection a known number of pancreases were incubated at 37° C for 1 h in 1 ml. of medium containing 10<sup>5.5</sup> ID<sub>50</sub> of FMDV (type O; strain VI). A sample of medium containing virus but no tissue was similarly incubated. Titrations of residual virus after incubation with and without pancreases using 5-7-day-old *P* strain mice gave end points not significantly different from each other (calculated by the method of Reed and Muench<sup>6</sup>). If allowances are made for the error of such titrations, the maximum amount of virus which could have been absorbed by the batch of tissues would not be greater than 10<sup>3.7</sup> ID<sub>50</sub>, and this would be considerably reduced by thermal inactivation during incubation. Uninfected control pancreases were similarly incubated in virus-free medium. The infected pancreases were washed twice with phosphate buffered saline (pH 7.2) at 37° C for 2 min, in groups of 3 on rayon strips mounted on stainless-steel gauze. Each group of three pancreases was placed in a separate wide-mouthed transfusion bottle containing 30 ml. of medium which was then gassed for 2-3 min with 5 per cent carbon dioxide in oxygen and incubated at 37° C. The medium consisted of 80 per cent Eagle's basal medium<sup>7</sup>, 10 per cent calf serum and 10 per cent 14-day chick embryo extract and was changed on the third day.

The virus content of each group of three infected pancreases was determined at intervals for up to five days, the pancreases being washed in phosphate-buffered saline (pH 7.2) and stored at -20° C pending titration. Parallel cultures for histological studies were fixed in 10 per cent neutral buffered formalin, dehydrated and embedded in paraffin wax. Sections 7µ thick were cut at intervals of 20-30µ through the pancreas and stained with haematoxylin and eosin. In all 45 infected and 16 uninfected pancreases were cultured.

Virus was found to be present up to the third day *in vitro*, but was recovered only once after this time. Table 1 summarizes the results of two experiments. It is evident that the pancreatic explants were able to support virus multiplication and the total amount of virus rose to a

\*Mean weight of 6 pancreases (6-7 day old mice) was found to be 20 mg

peak at about 50 h, much of the virus being released into the medium. Histologically, lesions attributable to FMDV could not be detected. Apart from occasional areas of necrosis in older cultures, both infected and control pancreases appeared fully viable, but with continued culture the acinar lumen increased in size and the cells became flattened and atrophic, forming duct-like structures (Figs. 1 and 2). Zymogen granules decreased in number during the period of culture. This is in contrast to the active synthesis of zymogen granules observed in cultured foetal pancreases<sup>6,7</sup>.

It can be concluded that the 6-7-day-old mouse pancreas cultured *in vitro* produces moderate yields of FMDV but without specific cytopathic changes. A similar growth of FMDV without the development of cytopathic effects has been observed in polygonal cell monolayers derived from bovine tongue epithelium<sup>10</sup>.

The transfer of results obtained in tissue culture to the whole animal can only be made with caution; but it

is possible that some multiplication of FMDV may occur in the pancreas of the suckling mouse *in vivo* in spite of the absence of demonstrable pathological lesions there.

I thank Dr. J. B. Brooksby and Dr. H. Platt for their advice and Mrs. D. Read for the histological preparations.

## VETERINARY SCIENCE

### Diurnal Variation in the Diet selected by Free-grazing Sheep

THE use of oesophageal fistulae has facilitated work on the diet selected by grazing ruminants. Three experiments at this laboratory with free-grazing sheep have shown marked diurnal changes in the nitrogen content of the diet selected by Merino wethers.

In experiment A, ten two-year-old Merino wethers fitted with oesophageal fistulae continuously grazed a *Phalaris tuberosa*/white clover (*Trifolium repens*) pasture for two months during summer. During the last five days, samples of approximately 20 g of dry matter were collected through the fistula for two 20-min periods starting at 0830 h and 1500 h. The sheep were not deliberately fasted before the samples were collected. The samples were dried at 70°C in a forced draught oven and analysed for nitrogen and organic matter. The mean nitrogen contents expressed as a percentage of the organic matter for the morning and afternoon samples were 3.38 and 3.99 per cent respectively, the difference being significant ( $P < 0.05$ ). There were also significant differences between sheep ( $P < 0.001$ ) and a significant day  $\times$  time of day interaction ( $P < 0.001$ ). The difference between sheep has been observed on many occasions, even when, as in these trials, the sheep were of similar sex, breed and age, and had been originally drawn at random from a single flock.

In experiment B, five Merino wethers similar to those used in exp. A were run on a ryegrass (*Lolium perenne*)/white clover pasture for several months during winter. Samples were taken on two separate days, starting at 0830, 0910, 1140, 1430 and 1710 h. The nitrogen content of samples collected at different times throughout the day differed significantly ( $P < 0.01$ ), rising rapidly during the morning and levelling out during the afternoon. It was possible to fit a significant quadratic regression equation ( $P < 0.01$ ) to this trend:

$$y = 3.01 + 0.1187x - 0.00783x^2 \quad (1)$$

where  $y$  is the mean nitrogen content of the sample expressed as a percentage of the organic matter, and  $x$  is the time elapsed in hours from dawn (0830 h). The values are shown in Fig. 1.

Although there were significant differences between sheep ( $P < 0.01$ ) and between days ( $P < 0.05$ ), and a significant interaction between days and time of day ( $P < 0.05$ ), the slope of the relationship between dietary nitrogen concentration and time of day could be combined between sheep and between days.

In experiment C, a *Phalaris tuberosa*/cocksfoot (*Dactylis glomerata*)/white clover sward was continuously grazed

Fig. 1. Relationship between nitrogen content of diet selected by grazing sheep and time of day. ●, Exp. B; ○, exp. C.

at four stocking intensities ranging from 1 to 13 sheep per acre for eighteen months, resulting in a wide range in herbage availability. On each pasture a fistulated Merino wether similar to those used in the previous experiments had been grazed with the other sheep. A second fistulated sheep was then introduced, which was identical with the first except that it had previously grazed a ryegrass/lover pasture. Ten days later, samples were taken from all fistulated sheep on two separate days at similar times to those used in exp. B.

As observed in exps. A and B, there were significant differences ( $P < 0.05$ ) between samples collected at different times of day, and again it was possible to fit a significant ( $P < 0.05$ ) quadratic equation to this trend which is shown in Fig. 1:

$$y = 3.32 + 0.143x - 0.0108x^2 \quad (2)$$

There were also significant differences in the nitrogen content of the diet between the different pastures ( $P < 0.05$ ) and between the sheep which had been grazed on the experimental pastures for many months and those which had not ( $P < 0.01$ ); the mean value for the former was 3.72 per cent and for the latter 3.52 per cent nitrogen. This phenomenon cannot at present be explained, but similar differences have been observed on other occasions.

The regression coefficients given in equation (2) did not differ significantly between paddocks or between the two groups of sheep. Furthermore, those derived in exp. B could be combined with those in exp. C, the pooled coefficients being  $+0.131$  for  $x$ , and  $-0.00939$  for  $x^2$ .

Information on diurnal trends in selection by grazing ruminants is limited. Taylor and Deriaz<sup>1</sup> report investigations in which samples of herbage were collected from one steer fitted with a rumen fistula by manually collecting the feed boluses as they entered the reticulo-rumen. They found no consistent trend throughout the day under continuous grazing. Since in the three experiments reported here such trends were statistically significant and of similar magnitude, it would be of value to define those conditions in which they do occur. Until these conditions are clearly established, it would seem prudent to consider the possibility of diurnal trends when designing experiments to examine selection by grazing sheep. This may also be necessary when a representative sample of the daily intake is required, but it may be difficult to establish an optimum sampling time for this purpose because sheep tend to graze at specific times of day<sup>2</sup> and possibly at different rates at these times. Further work will be necessary to ascertain whether the changes observed reflect

diurnal changes in the composition of the herbage organic matter, or in the parts of the plant or species of plant selected.

## SOIL SCIENCE

### Contribution of Organic Matter to the Cation Exchange Capacity of Soils

THE cation exchange capacity of soils is due to inorganic constituents such as clay minerals, hydrous oxides, primary and secondary minerals and to organic matter. Estimates of the contribution of organic matter are usually made by determining the cation exchange capacity of soils before and after destruction of organic matter. Using this approach, Gorbunov<sup>1</sup> estimated that organic matter accounted for between 30 and 80 per cent of the cation exchange capacity of plough-depth layers of a number of Russian podzol soils.

I have recently re-examined this problem in a more direct fashion, that is, by determining exchangeable hydrogen (which in this case is equivalent to cation exchange capacity) in extracted and purified organic matter and found that the cation exchange capacity due to organic matter was considerably higher than that indicated by the 'difference' method.

For this purpose, soil samples taken by  $B_1$  horizons of imperfectly drained podzols, such as Armadale, are especially suited because: (a) practically 100 per cent of the organic matter can be extracted; (b) the extracted organic matter can be purified with relative ease; (c) we have assembled a considerable amount of information on the distribution of functional groups in and chemical properties of this type of organic matter<sup>2</sup>.

The soil sample contained 10.0 per cent organic matter, 10.1 per cent  $Al_2O_3$ , 2.9 per cent  $Fe_2O_3$ , 76.5 per cent  $SiO_2$ , 1.07 per cent 'free'  $Al_2O_3$ , and 0.91 per cent 'free'  $Fe_2O_3$ . It contained 10 per cent clay, which was predominantly illite. The cation exchange capacity was measured with N ammonium acetate solution adjusted to pH 7 (ref. 3), before and after destruction of the organic matter with increments of hydrogen peroxide. Methods of extraction and purification of organic matter were the same as those described previously<sup>2</sup>. Exchangeable hydrogen in the extracted and purified organic matter was determined by shaking with an excess N ammonium acetate solution at pH 7 and measuring the acetic acid liberated.

As shown in Table 1, the method based on difference measures only one-fifth of the cation exchange capacity that might be due to organic matter. Since for each milliequivalent of exchangeable hydrogen in the organic matter 3.6 millimoles of Fe+Al were available in this soil, it is very likely that the remaining exchange sites were blocked by ions or hydrous oxides of these constituents. In addition, reactions of organic exchange sites with silicon and/or compounds of silicon are also within the realm of possibilities. Conversely, we have been able to eliminate practically all the exchangeable hydrogen in the extracted and purified organic matter by interaction with sufficient ions or hydrous oxides of iron and aluminium. We have obtained results similar to those shown in Table 1 with soil samples taken from other podzol  $B_1$  horizons.

From the information presented here the following is suggested: (1) Reliable estimates of the contribution of organic matter to the total cation exchange capacity

Table 1. CATION EXCHANGE CAPACITY VALUES FOR ARMADALE B<sub>2</sub> SOIL AND ORGANIC MATTER

Material	Mequiv./ 100 g soil	% Cation ex- change capacity
'Difference' method		
Unirradiated soil	18.7	100.0
Soil after destruction of organic matter (= inorganic portion)	5.7	30.5
Due to organic matter	13.0	69.5
Organic matter extracted and purified	5.7	8.1
Inorganic portion		
Extracted and purified organic matter (humic + fulvic acids)	65.0	91.9
	70.7	100.0

cannot be made by the 'difference' method. Because in most predominantly inorganic soils only 20–30 per cent of the organic matter can be extracted, meaningful estimates of the organic exchange capacity can be made only in those soils in which either the bulk of the organic matter can be extracted, such as podzol B<sub>2</sub> horizons, or in organic soils where most of the inorganic constituents can be extracted from the organic matter. (2) The results in Table 1 suggest that in the case of soils containing appreciable amounts of organic matter two types of cation exchange capacities should be considered: (a) 'measured' cation exchange capacity as determined by exchange with NH<sub>4</sub><sup>+</sup> or any other ion one might choose to use; (b) 'potential' cation exchange capacity, that is, 'measured' cation exchange capacity plus cation exchange capacity due to blocked organic exchange sites which are inaccessible to or do not react with exchange ions. These blocked sites can be unlocked and measured by methods such as have been used in this investigation. Thus, the 'potential' cation exchange capacity of soils might be several times greater than the 'measured' one. From the foregoing a practical application is suggested: if organic exchange sites presently blocked by inert iron and aluminium compounds could be filled with ions more beneficial to plant nutrition, soil productivity might be increased.

## MISCELLANY

### Probability of Life

PROF. H. F. BLUM has given reasons for believing that the probability of the development of life up to the present human cultural level on our planet is unlikely to exceed  $10^{-18}$  (ref. 1). His arguments may well be valid if they are supposed to apply to our specific civilization with its Ford cars and hybrid maize and antifluoridation societies. There is, however, a simple fallacy involved when Prof. Blum suggests that this minute figure should "give our imagination pause in peopling the universe with living things, particularly with 'intelligent' life approaching closely the characteristics of men".

The probability of any set of bridge hands being dealt twice running to the same four people from well-shuffled packs is in the region of  $10^{-31}$ . There is no comparable improbability that the second deal will yield something usable for the purpose of playing bridge.

Since the beginning of life on this planet, Prof. Blum suggests that not less than  $10^9$  successful mutations have gone to the making of the present million or so living species.

Hence he deduces that the probability of biological evolution having reached its present state is of the order

of  $10^{-9}$ . Even if we grant this numerical deduction for the present particular set of species—though for this  $10^{-9}$  seems incredibly large—it neglects the fact that if any one of the successful mutations had not occurred, some other mutation would have been successful. Without going into any numerical detail at all, it is surely clear that, once a mutable life has started, the probability that some assortment of living species should exist at any future time is not  $10^{-9}$  but unity (assuming that no catastrophe great enough to sterilize the entire planet occurs). Following Prof. Blum in treating man as a special case, there seems no reason for thinking that the rest of the present living species are unexpectedly complex in number or variety; that they are more than a very ordinary bridge hand.

The development of a human level of intelligence might be considered seriously as a highly improbable event, but such palaeontological evidence as we have does not support such a consideration. Creatures in widely separated groups, and even in different phyla, have shown a continuous increase in brain size with time, so that though specific mutations may have been improbable, the kind of mutation leading to this was not. Even at the immediately pre-human level there seem to have been at least three evolutionary lines which learnt the use of tools.

Finally, Prof. Blum multiplies his improbability by a further factor of  $10^{-4}$  to represent the improbability of the 'cultural mutations' leading to our present state. Again, if he is considering the probability that the world should have the particular pattern of nations and cultures that it has, his factor of  $10^{-4}$  is probably far too large, but surely some kind of advanced culture had a probability approaching unity once the use of tools by creatures of human intelligence was established some tens of thousands of years ago.

A different path for some of the most vital 'cultural mutations' might have changed the rate of development—in either direction—as well as the final form, in quite major ways, but the ultimate development of a highly complex civilization was surely inevitable.

We do not yet know enough to be at all confident of the probability that life should arise in the first place in suitable conditions—Prof. Blum sets this as  $10^{-8}$ —but once this is done, though there may well be  $10^{18}$  or more major routes by which it can develop to organized intelligence, the chance of one of these routes being eventually found is surely very large indeed.

J. H. FREMLIN

Department of Physics,  
University of Birmingham.

<sup>1</sup> *Nature*, 206, 131 (1965).

DR. FREMLIN's analogy to probabilities of bridge hands seems far from applicable to evolutionary processes of the kind considered in my article. Before dealing a bridge hand the pack is thoroughly shuffled to avoid retention of patterns of arrangement of the cards. In evolution each step is predicated on an existing pattern which has been formulated in the course of previous evolutionary steps, the pattern being copied (by one means or another) and so retained between steps. Thus, the probability of a given step is to be reckoned in terms of existing pattern, not in terms of a shuffled arrangement as for a bridge hand. The analogy to computer operation used in my article seems more suitable and leads to a very different point of view.

## APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

**RESEARCH ASSISTANT (honours graduate) IN THE DEPARTMENT OF APPLIED MATHEMATICS**—The Registrar, University College of Wales, Aberystwyth (August 10).

**LECTURER IN COMPUTER SCIENCE IN THE DEPARTMENT OF MATHEMATICS**—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (August 13).

**LECTURER (preferably with interests in fluid mechanics or heat transfer) IN MECHANICAL ENGINEERING**—The Secretary, The University, Edinburgh (August 14).

**UNIVERSITY DEMONSTRATOR (with an appropriate honours degree and post-graduate teaching and research experience) IN ANIMAL PHYSIOLOGY AND GENETICS**—The Secretary, School of Agriculture, University of Cambridge, Downing Street, Cambridge (August 18).

**KEEPER (with an appropriate university degree and/or the Museums Association Diploma, and preferably museums experience) OF ARCHAEOLOGY IN THE MUSEUM AND ART GALLERY DEPARTMENT**—The Town Clerk, Town Hall, Bolton (August 20).

**LECTURER IN EPIDEMIOLOGY AND PREVENTIVE MEDICINE**—The Secretary of the University Court, The University, Glasgow (August 20).

**LECTURERS OR ASSISTANT LECTURERS (3) (with interests in any of the branches of electrical engineering, but one of the posts may be particularly concerned with physical electronics, in connection with the recently inaugurated honours course in physics and electronic engineering) IN MICROELECTRONICS IN THE FACULTY OF SCIENCE**—The Registrar, The University, Manchester, 13, quoting Ref. 153/65 (August 20).

**RESEARCH ASSISTANT IN THE DEPARTMENT OF CIVIL ENGINEERING, to work on problems of creep in concrete**—The Registrar, King's College (University of London), Strand, London, W.6.2 (August 23).

**RESEARCH ASSISTANT (with relevant research experience of some aspects of turbulent flow) IN THE DEPARTMENT OF AERONAUTICAL ENGINEERING to take a leading part on a research project supported by the Science Research Council on the turbulent mixing of cold and hot jets with an external stream**—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (August 23).

**ASSISTANT DIRECTOR OF RESEARCH (with a degree in agriculture or agricultural science, or suitable postgraduate qualifications in these subjects, and substantial experience of the agriculture of developing countries) IN COMPARATIVE AGRICULTURE**—The Secretary, School of Agriculture, The University, Downing Street, Cambridge (August 25).

**RESEARCH MICROSCOPIST (with an honours or ordinary degree or an equivalent qualification, and experience in the use of the electron microscope in biological research) IN THE DEPARTMENTS OF BIOLOGICAL CHEMISTRY AND PHYSIOLOGY, to take charge of the electron microscope serving these two departments, and, for the present, certain others**—The Secretary, The University, Aberdeen (August 27).

**LECTURER OR SENIOR LECTURER IN GEOGRAPHY AT THE UNIVERSITY OF TASMANIA, AUSTRALIA**—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 27).

**TECHNICAL STAFF EDUCATION OFFICER (with a university degree in one of the physical or biological sciences, broad experience of science teaching, and good experimental technique) IN THE FACULTY OF SCIENCE**—The Registrar, The University, Hull (August 27).

**COMPUTER MANAGER (graduate with experience of computer operation and administration) IN THE COMPUTING CENTRE**—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (August 28).

**ASSISTANT LECTURER (with qualifications in probability theory and statistics) IN THE DEPARTMENT OF MATHEMATICS**—The Secretary, University of Lancaster, Bailrigg House, Lancaster (August 31).

**EXPERIMENTAL OFFICER (with a degree or equivalent qualification or considerable experience in the field of single crystal and powder phosphor preparation) for the supervision of a crystal growing laboratory in the Physics Department**—The Registrar, The University, Hull (August 31).

**LECTURER/ASSISTANT LECTURER (preferably with experience in the field of magnetic resonance, gas discharges or studies on the mechanical properties of materials) IN THE DEPARTMENT OF PHYSICS**—The Registrar, The University, Keele, Staffs (August 31).

**SENIOR LECTURER OR LECTURER IN PHILOSOPHY AT VICTORIA UNIVERSITY OF WELLINGTON, NEW ZEALAND**—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 31).

**SENIOR RESEARCH ASSOCIATE (graduate in agriculture, veterinary science or zoology, with some postgraduate experience in helminthology) IN PARASITOLOGY, to work on the biology of parasites of the respiratory system of sheep**—The Registrar, University of Newcastle upon Tyne, 6 Kensington Terrace, Newcastle upon Tyne, 2 (August 31).

**TUTOR IN THE DEPARTMENT OF PURE MATHEMATICS**—The Registrar, University College of Wales, Aberystwyth (August 31).

**ASSISTANT LECTURER OR LECTURER IN MATHEMATICAL STATISTICS IN THE DEPARTMENT OF APPLIED MATHEMATICS**—The Registrar, The University, Liverpool, quoting Ref. CV/196 (September 1).

**LECTURER (science graduate) IN BACTERIOLOGY AT QUEEN'S COLLEGE**—The Secretary, University of St. Andrews, c/o Queen's College, Dundee (September 1).

**LECTURER (with experience in soil mechanics and concrete technology and allied experience in related fields) IN CIVIL ENGINEERING MATERIALS, to take charge of the Materials and Building Science Section of the Department of Civil Engineering**—The Registrar, The University, Newcastle upon Tyne 2 (September 1).

**RESEARCH ASSISTANT (scientific or medical graduate) IN HUMAN ALLERGY IN THE DEPARTMENT OF PHARMACOLOGY for work involving research into pharmacological and biochemical aspects of human allergy**—The Professor of Pharmacology, University College, Gower Street, London, W.C.1 (September 1).

**LECTURERS OR SENIOR LECTURERS IN THE SCHOOL OF BOTANY, UNIVERSITY OF MELBOURNE, AUSTRALIA**—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 4).

**DATA PROCESSING OFFICER to assist in the mechanization of financial and other administrative processes**—The Deputy Secretary, The University, Southampton (September 11).

**OFFICIAL FELLOW AND TUTOR IN PURE MATHEMATICS**—The Master, St Catherine's College, Oxford (September 11).

**CLINICAL LECTURER IN THE DEPARTMENT OF PSYCHIATRY**—The Assistant Registrar, The Medical School, University of Birmingham, Edgbaston, Birmingham, 15 (September 14).

**CHAIRS (2) OF PATHOLOGY AT THE UNIVERSITY OF MELBOURNE, AUSTRALIA**—The Association of Commonwealth Universities (Branch Office), Marl-

borough House, Pall Mall, London, S.W.1 (Australia and London, September 15).

**SENIOR LECTURER/LECTURER IN THE SCHOOL OF ANATOMY, UNIVERSITY OF NEW SOUTH WALES**—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 17).

**LECTURER (with a first degree in mathematics, physics or engineering and appropriate postgraduate experience) IN CYBERNETICS IN THE DEPARTMENT OF APPLIED PHYSICAL SCIENCES**—The Registrar (Room 23, O.R.B.), The University, Reading, quoting Ref. AP8.13 (September 18).

**LECTURER/SENIOR LECTURER IN METALLURGY AT THE UNIVERSITY OF NEWCASTLE, NEW SOUTH WALES, AUSTRALIA**—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (September 20).

**LECTURER (suitably qualified person with special interests within any of the main branches of chemistry) IN CHEMISTRY AT THE UNIVERSITY OF QUEENSBURY, CHRISTCHURCH, NEW ZEALAND**—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 20).

**LITERARIAN**—The Secretary, The University, Aberdeen (September 20).

**MYCOLOGIST (with a good honours degree) to work on soil-borne diseases of cereals**—The Secretary, Rothamsted Experimental Station, Harpenden, Herts, quoting Ref. 1051/61 (September 20).

**POST-DOCTORAL FELLOWS (2) (organic chemists with a Ph.D. or equivalent degree in chemistry) IN ORGANIC CHEMISTRY AT THE UNIVERSITY OF QUEENSBURY, CHRISTCHURCH, NEW ZEALAND, to carry out synthetic and kinetic research on derivatives of ascorbione**—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 20).

**PROFESSOR OF STATISTICS IN THE SCHOOL OF MATHEMATICS, UNIVERSITY OF MELBOURNE, AUSTRALIA**—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 20).

**CHAIR OF EDUCATION AT THE UNIVERSITY OF MELBOURNE, AUSTRALIA**—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (October 1).

**SENIOR LECTURER (with special interests in physical oceanography, including dynamic oceanography and/or marine geology) IN OCEANOGRAPHY, and a LECTURER (preferably with a special interest in enzymology) IN BIOCHEMISTRY**—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (October 1).

**CHAIR OF PHILOSOPHY AT MONASH UNIVERSITY, MELBOURNE, AUSTRALIA**—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 5).

**SENIOR LECTURER IN MEDICINE (Neurology)**—The Secretary, The University, Edinburgh (October 13).

**CHAIR OF GENETICS**—The Registrar, University College of Swansea, Singleton Park, Swansea (October 20).

**AGRICULTURAL CHEMIST (national of the United Kingdom or the Republic of Ireland, with an honours degree in chemistry or agricultural chemistry) IN ZAMBIA, to supervise routine chemical analysis for agricultural purposes and to undertake development or modification of analytical methods, with special reference to foods and feeding stuffs**—The Appointments Officer, Ministry of Overseas Development, Room 301, Hans House, Stag Place, London, S.W.1, quoting R.O. 214/122/010.

**ASSISTANT EXPERIMENTAL OFFICER OR EXPERIMENTAL OFFICER (graduate with a pass degree in agriculture or agricultural science) to assist in investigating the role of conservation in intensive livestock feeding**—The Secretary, The Grassland Research Institute, Hurley, Maidenhead, Berkshire.

**ASSISTANT PHYSICIAN, RADIO GRADE (previous hospital experience is not essential) to work in the Radiotherapy Department and the Clinical Isotope Laboratory**—The Group Secretary, Saint Mary's Hospital, Milton Road, Portsmouth.

**ASSOCIATE PROFESSORS (2) (with an honours degree and experience in the planning and direction of groups engaged in research) IN CHEMICAL TECHNOLOGY AT THE UNIVERSITY OF BUENOS AIRES, ARGENTINA (one from February 1966, and the other from February 1967)**—The Recruitment Division, The British Council, 65 Davies Street, London, W.1, quoting Ref. C/65/UNI/60-61.

**CHAIR IN COMMUNICATION THEORY; and CHAIR IN ACOUSTICS**—Dr G. L. d'Ombra, Chairman, Electrical Engineering Department, McGill University, Montreal, Canada.

**DEMONSTRATOR (with an honours degree in mechanical engineering or physics, or ordinary degree, H.N.D. or H.N.C. and some experience in a relevant subject) IN THE THERMODYNAMICS AND FLUID MECHANICS DIVISION OF THE MECHANICAL ENGINEERING DEPARTMENT, to carry out research into separated supersonic flows and assist in the fluid mechanics laboratory teaching in the department**—The Registrar, College of Science and Technology (University of Manchester), Backville Street, Manchester, 1.

**RESEARCH SPECIALIST (with experience of transistor techniques) to take charge of the electronic workshop in the Department of Veterinary Physiology**—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh.

**FELLOWS AND RESEARCH ASSISTANTS IN THE ASTBURY DEPARTMENT OF BIOPHYSICS. Fields of study include the biochemistry of proteins and protein polysaccharide systems; the electron microscopy of tissues and macromolecular systems**—The Registrar, The University, Leeds, 2.

**GRADUATE PHYSICAL CHEMIST to carry out research into the control of polymer properties, through graft copolymerization**—The Director, Arthur D Little Research Institute, Inveresk, Musselburgh, Midlothian.

**LECTURER OR ASSISTANT LECTURER (preferably with research interests in forensic chemistry, toxicology or enzymology) IN CHEMISTRY IN THE DEPARTMENT OF PHYSIOLOGY**—The Secretary, The Royal Veterinary College (University of London), Royal College Street, London, N.W.1.

**MASTER (preferably with a knowledge of or interest in S.M.P.) to teach Mathematics to all levels**—The Director of Studies, Nautical College, Pangbourne, Berkshire.

**POST-DOCTORAL FELLOW IN ORGANIC CHEMISTRY**—The Registrar, The University, Manchester, 13.

**POST-DOCTORAL FELLOW IN SOLID STATE PHYSICS for work on the transport and optical properties of molecular crystals**—The Registrar, University of Leicester, Leicester.

**RESEARCH ASSISTANTS (2) IN THE DEPARTMENT OF CHEMISTRY AND CHEMICAL ENGINEERING, Southampton College of Technology, for work on separatory and kinetic problems associated with nitrogen and sulphur compounds in petroleum**—The Chief Education Officer (Ref. 56/BA), Civic Centre, Southampton.

**RESEARCH FELLOW (graduate in engineering, science or mathematics) IN THE DEPARTMENT OF AIRCRAFT DESIGN, to carry out theoretical and experimental work in the field of optimum structures**—The Registrar, The College of Aeronautics, Cranfield, Bedford.

SENIOR PHARMACIST (full or part-time)—The Physician Superintendent, Oakwood Hospital, Maidstone, Kent.

SENIOR RESEARCH FELLOW or RESEARCH FELLOW (suitably qualified graduate interested in theoretical work in support of concurrent experimental programmes) IN THE DEPARTMENT OF BIOMEDICAL AND CONTROL ENGINEERING, to be concerned with Government-sponsored research into techniques of device analysis and synthesis using analogue networks in conjunction with analogue/digital computer methods—The Registrar, The College of Aeronautics, Cranfield, Bedford.

## REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

### Great Britain and Ireland

- Proceedings of the Royal Irish Academy. Vol. 64, Section A, No. 4: The 1-Method for Acoustic Rectangular and Skew Plates. By Patrick M. Quinn. Pp. 49-84. 10s. Vol. 64, Section A, No. 5: Correlation of Spectroscopic and Electrical Properties of Glow Discharges Through Iodine. By B. S. Stewart, G. A. Woolsey, J. M. Brown, J. B. M. Coulter and K. G. Hume. Pp. 85-91. 1s. 6d. Vol. 64, Section B, No. 4: The Upper Carboniferous (Wamurian) Stratigraphy North-East of Castle Island, Co. Kerry, Ireland. By Timothy P. Brennan. Pp. 41-64 + plates 5 and 6. 6s. 6d. Vol. 64, Section B, No. 5: The Lower Carboniferous Stratigraphy of the Buttevant Area, Co. Cork. By R. G. S. Hudson and M. R. Philcox. Pp. 65-79 + plates 7, 4s. Vol. 64, Section B, No. 6: The Relation Between the Extracellular Concentration of Glucose and the Combination of Glucose in Normal and Diabetic Tissue. By J. M. O'Connor. Pp. 81-88. 1s. 6d. Vol. 64, Section B, No. 7: Notes on the Hemiptera, Coleoptera, Diptera, and other Invertebrates of the Burren, Co. Clare, and Inishmore, Aran Islands. By I. Lanebury. Pp. 89-115. 5s. (Dublin: Royal Irish Academy, 1965.) 46
- Admiralty Tidal Handbook, No. 3: Harmonic Analysis for Short Period Observations. Pp. 24. (H.D. 529.) (London: Hydrographer of the Navy, 1964.) 21s. net 46

## SCIENTIFIC AND INDUSTRIAL RESEARCH

THE final report of the Council for Scientific and Industrial Research, covering the year 1964\*, is marked by the same calm dignity which characterized its previous annual report amid the near hysteria with which the Trend Report had been received in some quarters. The report is brief, about a third of its pages being devoted to a retrospect of the Department's work, and this makes it the easier to pay fitting tribute to the achievements of the Council and of its predecessor, the Advisory Council for Scientific and Industrial Research, appointed in July 1916. The work of the Department has contributed greatly to the place which science and technology now hold in the Nation's affairs, and while the establishment of the Council was due largely to the initiative of Lord Balfour, it was fitting that on July 14, when the House of Commons considered in Committee the Civil Estimates for the Ministry of Technology, Sir Henry Legge-Bourke, at least, should pay tribute to those who have worked over the years in the Department and achieved these results.

As the Research Council itself observes, most of the broad lines of its present activities were foreshadowed forty years ago by the Advisory Council for Scientific and Industrial Research, and it is in the tactics used to pursue this programme and to maintain flexibility to meet changing circumstances that marked developments have occurred. Support for training graduates in the methods of research, and support for research projects in universities and colleges, have gone hand in hand since 1916, although the scale of this support did not increase between the two World Wars, only 119 training awards being current in 1939-40, compared with 132 in 1920. After 1945 development was much more rapid, and in 1959-60 525 research grants totalling £916,000, and 2,464 training awards, were current—an almost twenty-fold increase since 1939-40. On November 1, 1964, there were almost 1,200 current grants, totalling more than £13 million, and more than 5,000 training awards.

The National Physical Laboratory has always been the largest of the Department's establishments, although some of the Laboratory's research divisions have since formed, for example, the nucleus of the National Engineering Laboratory and the Radio Research Station. The report does not refer to the National Chemical Laboratory, which in future is to become part of the National Physical Laboratory, and, while there is a reference to the Building Research Station as one of the Department's oldest and largest establishments, no reference is made to the problem of its future location, on which a final decision has yet to be taken. The Council does, however, comment that during the Department's existence the general policy of the Government has been to place civil research outside the administrative responsibility of policy-making departments. The one notable exception—aviation research—has not been a momentous success. Expenditure on the research stations increased from £346,000 on six stations in 1925 to almost £10 million on fifteen stations in 1964.

Concerning the growth of the co-operative industrial research associations, which now number more than fifty

compared with eighteen at the end of July 1920, the Council comments on the various arrangements for grants. However, the report does not discuss the functions or work of the associations generally. Nevertheless, the Council does comment on the ways of devising new forms of Government support and the use of multi-disciplinary teams to tackle many-sided problems and offset specialization in the basic training of research workers. The techniques of operational research have evolved during the Department's lifetime and in recent years have influenced the organization and methods of many applied research establishments and the ways in which they have sought to promote innovation in industry. In the past decade the Department's own Industrial Operations Unit has made a valuable contribution to higher productivity by demonstrating to a wide range of industry how operations can be simplified. Special reference is made to the studies of its Economics Committee in such industries as machine tools and shipbuilding and to the useful action they have promoted. This section of the report is strictly factual, and is supplemented by a tabulated list of developments over the years, which completes the account of the Department given by Sir Harry Melville in the monograph in the new Whitehall Series.

Dealing with activities during the year, the report points out that applications for research grants increased almost eight-fold between 1956-57 and 1963-64, and expenditure increased about ten-fold. It is estimated that these research grants at present represent some 10 per cent of recurrent expenditure by universities, from public funds, on scientific research. The Council suggests that this is a reasonable fraction, but it is growing. Accordingly, it is becoming more and more necessary continuously to examine and to discuss the division of responsibility between the universities and the research councils. Moreover, the proportion is high enough to justify the close concern manifest over the effect of any change in the organization of civil science. The Council also emphasizes the importance of directing attention to the problems of securing the best balance between different scientific disciplines in the work supported at universities now that science has become such an important instrument of national policy. The Council suggests that it is inevitable that the Government, through the University Grants Committee and the Research Councils, should offer (and the universities be prepared to accept) more guidance on how, by choice of subject and allocation of effort, universities can make their most effective contribution in scientific research. This is particularly necessary when the cost of research in one field is becoming very large and absorbing a significant part of the available resources, for example, in nuclear physics.

To encourage this development, the Council notes that its Research Grants Committee appointed four new sub-committees for technology to consider applications for grants, to select promising areas for investigation and to keep in touch with developments in Government laboratories and industry. During the academic year 1963-64 the Research Grants Committee considered 980 new applications for grants, totalling £10.5 million (excluding major capital grants), compared with 639 applications, totalling £6.3 million, in the previous year. Supplementary

\* Department of Scientific and Industrial Research. Report of the Research Council for the year 1964. Pp iv+70. (Cmd. 2706.) (London: H.M.S.O., 1965.) 5s. 6d. net. See also page 668 of this issue of *Nature*.

applications relating to existing major capital grants amounted to £821,000. The value of grants awarded has increased, but the gap between the number of good applications and the number of awards was slowly increasing. The 789 grants made totalled £5.4 million, and included 205 grants in applied science and technology, which were valued at £1.8 million: this compared with 517 grants amounting to £3.7 million in the previous year. The new sub-committee appointed the previous year in the field of computing science has already begun to influence this field of research, and the largest grant so far made is £110,000 to the University of Cambridge to establish a research group in computing science. This centre is only the first of a number that the Committee hopes to see established and working in this field. The Human Sciences Committee considered 61 new applications for grants, totalling £480,000, and made 42 awards, amounting to £221,000. This included, as an innovation, a grant for a regional study of the interaction of industrial, economic, social and demographic changes, which is to be carried out by four departments of the University of Liverpool.

To encourage further graduate training of people with industrial experience, the Council instituted during the year a series of new awards known as the Department of Scientific and Industrial Research Industrial Fellowships. These are intended mainly for postgraduate training in technological subjects and are designed for older men, normally of 26-30, who have at least three years' postgraduate industrial experience in British industry and who intend to return to work in industry after completing their training. The Fellowships carry a substantially higher rate of reward than the normal studentship, and are comparable with the salary that the Fellow could normally expect to command in industry or in a university, but within a maximum of £2,000; the Council hopes that the scheme will commend itself to industry as a co-operative enterprise. The Council also notes a further increase in the demand for studentships and fellowships, including a further increase in the number of new ones held abroad.

As regards the research stations, the Council comments on the report of the Review Committee which was appointed in 1963 to consider the functions of the Water Pollution Research Laboratory. While the Committee was satisfied with the work of the Laboratory, it saw a need for additional basic research, particularly in microbiology and in physics and physical chemistry, for in the Committee's view advances in basic knowledge in these areas were most likely to lead to radical improvements in the processes for treating sewage and industrial effluents. Arrangements are being made to implement the recommendations of the Review Committee, and during the year the Laboratory's study of the conditions of the polluted Thames atmosphere, which had occupied fifteen years, was completed. The closing stages of the work were greatly accelerated by the use of the *Deuce* computer at the National Physical Laboratory, where the effect of changes in the polluting load during recent years are still being followed and compared with those predicted from knowledge of such loads and of other factors which influence the condition of the water. The methods of computation developed at the Laboratory should be of value to the Port of London Authority in controlling discharge of polluting matter to the estuary and should make possible, for the first time in Britain, control of pollution by quantitative prediction of the effects of individual discharges.

The report notes, but does not comment on, the report of the Brundrett Committee on Technical Assistance for Overseas Geology and Mining. However, it does outline recommendations of the sub-committee appointed by the Steering Committee of the National Engineering Laboratory to examine and report on the needs of industry for improvements in design procedure, particularly in computer-aided design and in programming for numerically controlled machine tools. The sub-committee recommended that the National Engineering Laboratory should be the focal point for this work, and that steps should be taken immediately to make available a nationally recommended programme for continuous control of machine tools in two axes simultaneously, with step-by-step movement in a third orthogonal axis interposed. Moreover, the sub-committee believed that such an arrangement would stimulate further discussion of industry's needs and help to formulate similar proposals for a comprehensive programme. It also recommended full evaluation of the American Automatically Programmed Tools Programme from the technical and economic point of view, and the development of a general generator programme for post-processors. These recommendations have been endorsed by the Steering Committee. The report also notes the large increase in the computing capacity of the National Physical Laboratory during the year.

Considerable thought has been given by the Council to grant policy towards research associations. However, beyond asking the question whether the concept of an indefinite financial partnership between Government and industry is justified in all circumstances, the general or inherent effectiveness of the research associations is not considered, although the Council does suggest that the concept of Government partnership with vigorous and useful research associations should remain an important feature of policy. It believes also that the main function of a research association is as an essentially industrial research laboratory, to develop all the skills that it can in the interests of its industry and so secure continuing and expanding industrial financial support within the industry for co-operative research. Nine contracts have now been placed under the Advanced Computer Techniques Project, and the field of techniques originally envisaged is largely covered. Considerable importance is attached by the Council to the success of this project in establishing direct co-operation in this field between Government and industry.

During the year, the Council developed a campaign to implement the recommendations of the Feilden Committee on Engineering Design. Although the Committee on Engineering Design, when reviewing the position, thought that progress in implementing its recommendations in the education field had been disappointingly slow during the year, the Council suggests that this may be partly due to changes in organization which are taking place. The Committee itself was formally dissolved in October 1964. In this, its last report, the Council refers rather more fully to information activities and to the report of the working party which the Department was asked to set up by the Advisory Council on Scientific Policy regarding a national organization for scientific and technical information. The functions recommended for such a body by the working party are essentially those to be exercised by the Office for Scientific and Technical Information which the Government has since set up within the Department of Education and Science. While the Research Council comments that arrangements had been agreed to ensure the closest liaison between the

proposed new organization and the National Reference Library for Science and Invention, which is the responsibility of the British Museum, there is no reference to the continued delays in the establishment of this reference library. Neither here nor elsewhere is there any sign in official circles of the real urgency for either the new reference library or a national library policy.

Generally speaking, then, the final report of the Council for Scientific and Industrial Research is purely factual, with few exceptions such as have been noted. It makes little reference to future policy, nor does it comment on a number of the steps which the Government has taken with regard to the organization of civil science, on which some uneasiness, to say the least, is felt in scientific circles. That uneasiness could easily grow if there is undue delay in dealing with many of the tasks which the Council for Scientific and Industrial Research left uncompleted. What remains to be said is, however, a word of congratulation to the Council and its predecessor, and to those who have worked during the years to contribute to the growing understanding of the important place which science holds in our national life, not only in purely industrial but also in many social and economic matters. The extent to which science has now become a matter for national policy is in great part due to the success of the organization initiated forty years ago, largely as a result of Lord Balfour's foresight and understanding.

## EINSTEIN SPACES

### Einstein-Räume

(Mathematische Lehrbücher und Monographien. Herausgegeben von der Deutschen Akademie der Wissenschaften zu Berlin Institut für Mathematik. 11, Abteilung Mathematische Monographien, Band XVI.) Von A. S. Petrow. Pp. x+394. (Berlin: Akademie-Verlag, 1964.) 58 D.M.

THIS is a translation into German by Prof. H.-J. Treder of the Russian original, published in 1961. Prof. Petrow has himself revised and enlarged the original for this translation. The translator has increased the bibliography so that it now contains more than 500 references, and has supplied an appendix on the newest developments in the invariant representation of free gravitational fields and the propagation of gravitational waves.

The first chapter deals with tensor analysis in a Riemannian  $n$ -space; this material is conventional, except for a very detailed discussion of the principal axes of a tensor and an account of Lie groups. In Chapter 2 Einstein's field equations are set down after some historical preliminaries, and an Einstein space defined as one in which the usual vacuum field equations are satisfied. The chapter ends with a useful account of known exact solutions of the vacuum field equations, with or without the cosmological term: here we find the fields of Schwarzschild, Kottler, Weyl, Levi-Civita, Bach, Brinkmann, Kasner, Delsarte, Chou, Narlikar and Karmakar, Einstein and Rosen, Buchdahl, Verma and Roy, and some others.

Chapter 3 contains the matter for which Prof. Petrow is justly famous: Einstein spaces are classified. But here arises a source of petty confusion. It is really the 4-index Riemann tensor that is being classified, but in general that tensor has 20 independent components and defies classification. The vacuum field equations reduce that number from 20 to 10, and the classification proceeds. But then the author shows that if we take another related 4-index tensor (actually the Weyl tensor), it has only 10 independent components anyway (irrespective of

the field equations), and can be classified in just the same way. In fact, the title of the book is a bit of a misnomer, so far as the essentials of the classification-process are concerned: that process is more powerful than the title seems to imply.

Chapters 4 and 5 are devoted to groups of motions, and the known solutions mentioned above are reviewed in this light. Chapter 6 deals with conformal transformations of Riemannian spaces, and Chapter 7 with the Cauchy (or initial-value problem) *in vacuo*, for a mass-stream (or dust-cloud) and for a perfect fluid. In Chapter 8 special types of gravitational fields are discussed. These include separable fields ( $ds^2$  splits into a sum of quadratic forms with no co-ordinate occurring in more than one), fields which are separable as the result of conformal transformation, fields with central symmetry and axial symmetry, harmonic fields, cylindrical gravitational fields, and gravitational fields with boundary conditions. Many exercises are distributed throughout the book.

In the days when physicists made crucial experiments with the aid of sealing-wax and string, their physical concepts were merely refined analogues of things in the world about them. Those happy days are gone. Unless one is a mathematician, enjoying mathematics for its own sake, the choice is between a guilty conscience and a headache when it comes to the concepts on which gravitational theory is based. Most people prefer to batten down their consciences and use Newtonian concepts—absolute space and time, action at a distance with the inverse square law, the laws of motion—all indefensible. The conscientious mind must grapple with a mathematical theory which is impeccable in concept, but so complicated that what little comes out of it may seem scarcely worth the trouble. Some people compromise: working with Einstein's concepts, they try to fit Newtonian language to the results—for example, they see a 'force' in the quadratic term in the equations of a geodesic.

Prof. Petrow does not go in for compromise of that sort. With a clear conscience and no headache, he weaves the mathematical structure pertaining to Einstein's theory, without much apparent concern about physics. Nevertheless, I think he has hit the nail on the head for physicists by insisting that the 4-index Riemann tensor lies at the heart of the matter. This tensor is the gravitational field, just as Maxwell's vectors are an electromagnetic field. For a long time physicists did not like Maxwell's theory, but they have learned to think as he did. Any physicist who wants to think seriously about gravitation must think in terms of the Riemann tensor. Indeed, there is here a good analogy. A Maxwellian field *in vacuo* may be classified in terms of its two Lorentz-invariants ( $E \cdot H$  and  $E^2 - H^2$ )—when these both vanish we have the familiar radiation field. Petrow's classification of the Riemann tensor *in vacuo* (or of the Weyl tensor in general) is, algebraically, a much more erudite affair, but in principle it is similar—it is a question of seeking invariants.

This book is an obvious must for serious students of general relativity. It should be translated into English.

J. L. SYNGE

## PALAEARCTIC GRASSHOPPERS

### Locusts and Grasshoppers of the U.S.S.R. and Adjacent Countries

By G. Ya. Bei-Bienko and L. L. Mishchenko. Part 1: Pp. 400+xxi. Part 2: Pp. 291+xxi. Translated from the Russian. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1963.) 160s. the two volumes.

SINCE its appearance in 1951 the original version of this publication has been the standard work on the Acridoidea of the U.S.S.R. The language in which it was

published has, however, severely limited its usefulness to Western European entomologists, and this translation will be widely welcomed.

The two volumes deal with the three families Tetrigidae, Eumastacidae and Acrididae, and the areas treated includes Scandinavia, Germany, Austria, northern Yugoslavia, the satellite countries of Eastern Europe, Turkey, northern Persia, north Afghanistan, Mongolia, Palearctic China, Korea and northern Japan, as well as the whole of the U.S.S.R. As a result of this very broad scope a total of 833 species are covered by the work and over 40 per cent of them are known only from outside the U.S.S.R.

Vol. 1 begins with a useful introduction of some 70 pages, dealing with such topics as the morphology, biology, ecology and economic importance of grasshoppers and locusts, and this is followed by a bibliography with over 200 entries. The remainder of this volume is devoted to a systematic treatment of the Tetrigidae, Eumastacidae and all but two subfamilies of the Acrididae; these two subfamilies, Acridinae and Oedipodinae, form the subject of the second volume.

By far the greatest value of this work lies in the fully illustrated identification keys, which are provided for every level in the classification from family to subspecies, and are the result of years of painstaking study. As many characters as possible have been incorporated into these keys, and for categories below the level of genus no further descriptions are given.

Bibliographical references are given to all original descriptions and to other works of taxonomic importance. The account of each species includes a few measurements, a brief indication of its distribution, and references to any work on its biology. Drawings of whole insects are given for many species, representing a fair proportion of the genera; these drawings were excellent in the Russian edition (though not always well printed), but in the Israeli edition they are reduced in size and badly reproduced. Almost all the shaded illustrations have suffered in this way and represent the worst feature of the translated edition; they are, however, irrelevant to its main purpose.

Unlike their original counterparts, the two volumes are printed on good quality paper and are adequately bound. The Canadian orthopterist Dr. R. L. Randell has acted as technical consultant to the translators, and mistakes in translation resulting from the technicalities of entomology are few. The Russian abbreviations used for labelling the anatomical drawings in the introduction have been replaced by numbers; this has been carried out successfully in most cases, though there are a few minor errors.

In so competently bringing this valuable work, which comes near to covering all the Palearctic Acridoidea, to the English-speaking world, the Israel Program for Scientific Translations is to be warmly congratulated.

DAVID R. RAGGE

## SOCIAL HABITS OF WATER MOLECULES

### Water and Solute-Water Interactions

By Prof. J. Lee Kavanau. Pp. 101. (San Francisco and London: Holden-Day, Inc., 1964.) 5.50 dollars.

ASK the reflective person what water consists of, and the reply will probably be on the lines of two parts hydrogen to one part oxygen. Address the same question to one of to-day's science graduates and the answer will of course be more sophisticated (being very likely embellished with murmurings about dipole moment and ionization), but little enlightenment in terms of any structural arrangement among the myriads of jostling molecules can be expected. It is not that our teachers or students have been

remiss, but that no one knows for certain what a snapshot of water on a molecular scale would look like. It is not for lack of speculation either that our knowledge is so doubtful, for there has been great theoretical activity in the field of ice and water structure in the past twenty years, and to say the present outlook for solving the principal problems is promising is to do the minimum justice to the situation.

No devotee believes that water in bulk and in any state of aggregation consists of molecules so estranged as to form no mutual attachments, however temporary. After all, ice is crystalline, cold water is denser than ice, and steam is not a perfect gas. Modern approaches to the structure of water do not view the liquid as if it were a highly concentrated steam (although Callendar suggested water dissolved steam), but they favour instead a retention of ice-crystallinity in the liquid. One idea is that the act of melting makes some lattice-bond rotations so irregular that the continuity of the lattice cannot persist for more than a few molecular diameters. Increase of temperature then twists the lattice apart still more. On the other hand, it may be the intermolecular vibrations that overcome the unity of the lattice, so that individual molecules break free in increasing numbers as the temperature is raised and take up intermediate positions in the array that remains. Another view allows the water molecules a much greater degree of promiscuity, while satisfying a continual compulsion to assemble in very short-lived clusters of about 50 molecules each. Taking this concept to an extreme produces a molecular orderliness where there are only neat clusters, and water can justifiably be described as its own hydrate.

Prof. Kavanau had all these considerations in mind when he recently completed a monograph on the structure and functions of biological membranes, for he included a substantial discussion of water structure and of molecular and ionic segregation in aqueous solution. His discussion has now been published separately and on the whole has withstood extraction from its original context very well. A certain amount of biological connotation survives, but this is neither intrusive nor irrelevant, and the text can be read with profit by chemists and physicists. Prof. Kavanau's treatment is largely descriptive and avoids mathematics, but sets out to comment in detail on the successes and shortcomings of present-day theories. The text has been carefully produced and is well supported by up-to-date references and indexes. The reader should not be dismayed by some apparent confusion between atoms and protons in the opening pages, and need not be dispirited by Prof. Kavanau's concluding passages, where there is a glimpse ahead to formidable problems concerning the role of water in biochemical processes.

E. C. POTTER

## GLASS-CERAMICS IN U.S.S.R.

### Catalyzed Crystallization of Glass

Editor-in-Chief: E. A. Porai-Koshits. (The Structure of Glass, Vol. 3.) Authorized translation from the Russian by E. B. Uvarov. Pp. 208. (New York: Consultants Bureau, Inc., 1964.) 20 dollars.

CATALYZED Crystallization of Glass differs from Volumes 1 and 2 in this series which were reports of meetings where very varied topics were brought together under the heading of the "Structure of Glass". The concentration on the one topic has resulted in a volume which leaves a better overall impression than the earlier volumes. In all 44 papers are divided into four sections: (1) general aspects of the crystallization of glass (7 papers); (2) two-component systems (5 papers); (3) the  $\text{Li}_2\text{O}$   $\text{Al}_2\text{O}_3$   $\text{SiO}_2$  system (18 papers); (4) other three- and four-component systems (14). The book may therefore be taken as a

progress report on the development of glass-ceramics in the U.S.S.R. Glass-ceramics were introduced by Corning Glass Works in the late 1950's as 'Pyroceram'.

Glass ceramics are poly-crystalline materials in which the crystals are extremely small and in which very little glassy phase remains. The material is prepared as a glass and the article fabricated by glass-forming techniques; by subsequent heat treatment it is converted into a crystalline ceramic body. The art in formulating the glass composition is to arrange that a multitude of nuclei can be produced by heating at one temperature; on these nuclei crystals are caused to grow by subsequent heating at a higher temperature. At the present time, nucleation arising from the formation of minute drops of one liquid in another appears to find most support. This immiscibility often occurs as a metastable condition in a glass below the liquidus temperature of the normal phase-equilibrium diagram.

The review of V. N. Filipovich entitled the 'Initial Stages in the Crystallisation of Glasses and Formation of Glass Ceramics' covers the statistical mechanics of immiscibility in a binary mixture, and the importance of the region of composition where the second differential of the free-energy with respect to the concentration is negative (the so-called 'spinodal region') is stressed. Porai-Koshits considers that in order to obtain the uniform fine crystallization desired for glass ceramics crystallization must be preceded by the formation of regions with the stoichiometric composition of the future crystals, although sub-microscopic immiscibility does not always cause the glass to crystallize. This must be so because the opalescence which is caused by the liquid-liquid separation can be made to disappear by heating at temperatures well below the liquidus.

Porai-Koshits and his colleagues describe work on the detection of small-scale heterogeneities in glasses by low-angle X-ray scattering.

The low-angle scattering results reported indicate that very useful information can be obtained. For example, the scattering intensity at an angle of 10 min from specimens of a sodium borosilicate glass are given as 300, 65 and 20 pulses/min for heat treatment of 8 h at 600° C, 5 h at 530° C and 5 min at 750° C. The glass heated at 750° C was transparent and it was calculated from the X-ray scattering to have heterogeneities of 50 Å; this is said to be confirmed by the fact that pores of 50 Å radius are formed after leaching. Another interesting observation is that in glasses in the Na<sub>2</sub>O, SiO<sub>2</sub> system maximum heterogeneity is obtained at 11.5 per cent Na<sub>2</sub>O.

The light-scattering work reported is interesting; generally it is in agreement with the findings from low-angle X-ray scattering. Useful results are reported for Li<sub>2</sub>O—SiO<sub>2</sub> and Na<sub>2</sub>O—SiO<sub>2</sub> glass systems.

The rest of the volume is marred by lack of details of the compositions of the glasses studied. A standard Li<sub>2</sub>O—Al<sub>2</sub>O<sub>3</sub>—SiO<sub>2</sub> glass is referred to without further details; additions of TiO<sub>2</sub> are made between 2.0–11 per cent and these are described as though they were minor additions and TiO<sub>2</sub> is referred to as a catalyst. Podushko and Kozlova assert, without any proof, that the effect of TiO<sub>2</sub> is to cause the temperature regions for nucleation and crystallization to overlap.

Some glass-ceramics in the Li<sub>2</sub>O—Al<sub>2</sub>O<sub>3</sub>—SiO<sub>2</sub>+TiO<sub>2</sub> system can be produced which are transparent although nearly completely crystalline. Florinskaya and her colleagues suggest that the crystals in the transparent material are different from those in the opaque material although both have been prepared from the same glass.

Various papers describe the study of nucleation and crystal growth by the use of infra-red and Raman spectroscopy, differential thermal analysis, changes in physical properties with heat treatment, and measurement of dielectric losses. Altogether it is an interesting volume which shows that a very considerable effort is allocated

in the U.S.S.R. to the development of this new technology. Generally the translation and printing are good; six or so minor misprints were noted, but these did not appear to be misleading.

R. W. DOUGLAS

## MATHEMATICS OF DECISIONS

### The Theory of Decision-Making

An Introduction to Operations Research. By W. Sadowaki. Translated from the Polish by Eugene Lepa. Translation edited by H. Infeld and P. Knightfield. Pp. viii + 292. (London and New York: Pergamon Press; Warszawa: PWE—Polish Economic Publishers, 1965.) 60s. net.

THE science of operational research (operations research in America) is one which is assuming increasing importance, as decisions made by management have to be based on an ever more complex array of facts. Over the past quarter of a century mathematical methods, designed to assist in the efficient utilization of available resources, have been evolved, and there is now a well-developed mathematical theory covering the best defined problems of operational research.

Although some early studies in linear programming were carried out in the U.S.S.R., the major developments in the science have taken place in Western countries, and it is interesting to find a book on this subject originating in a socialist society. However, the contents of this book are as relevant in the West as in Poland.

The author declares that the work is intended chiefly for economists, and the use of mathematics is therefore limited, although a slight knowledge of differential calculus is assumed. A mathematician will not be satisfied, as many proofs are omitted; this in itself is not of great importance although one would have liked to have seen proofs included in an appendix, but it is unfortunate that the mathematical theory which is used is at times suspect, and, while the results obtained are correct, it would be a pity if economists were led to believe that methods presented here were mathematically sound. In particular, the description of the simplex method suffers because one set of variables is used alternately with two different meanings; thus on one page there appear apparently conflicting equations, and while the author does not confuse them, the inexperienced reader may well have difficulty. On another occasion, after stating his intention to prove a formula, the author, when faced with a formula similar to the one he wishes to obtain, but including an extra term, states that this term causes some difficulty, and thereupon makes the assumption it is zero: such a proof would be better omitted.

The presentation of the material is well thought out, and, were it not for defects in the English edition, would make for easy reading. The larger part of the book is devoted to linear programming, which is treated in an elementary manner, with an abundance of examples. The development is good, but unfortunately in his attempt to avoid complicated mathematics the author has not presented the simplex algorithm in its usual form, in which it is more suitable for computational purposes. The principle of duality and the significance of the dual variables are well explained, although the translation is bad and obscures the meaning in places. The method quoted for the solution of the transportation problem is rather tedious. Although the benefits of computers are mentioned in the introduction there is little reference to their use in the body of the work; indeed the methods presented throughout the linear programming section are more suitable for calculation with pencil and paper than with computers.

Shorter chapters follow, on the theory of queues, theory of games, statistical methods, and dynamic programming, the first three of which are well explained, usually by

means of examples. Dynamic programming is a subject too often obscured by difficult mathematics, and it is to be regretted that the example given here has been needlessly complicated for non-mathematicians by the use of a cost function itself involving an integral. Each chapter is concluded by a good review of the relevant literature, as it existed in 1959. The final chapter contains a brief survey of applications of operational research in Poland, where, it would appear, little work had been carried out by the date of the Polish edition.

Although this book may well have fulfilled a need when it was originally published in Polish, it does not contribute to the literature in English. Its merits have been lost by poor translation and frequent misprints, both factors which needlessly confuse the reader, and could have been rectified by an editor with a knowledge of the subject.

ANTHONY WRAN

## PROGRESS IN GERONTOLOGY

Advances In Gerontological Research

Edited by B. L. Strehler. Vol. 1. Pp. xi+410. (New York and London: Academic Press, 1964.) 96s. 6d.

THIS first volume of *Advances in Gerontological Research* contains a mixed collection of ten papers, mainly by American authors, which vary in length and the amount of detail thought to be appropriate. The chosen topics are wide-ranging, but concentrate more on the general biological than on the purely medical aspects of ageing. The psychological and sociological sides of the subject are omitted altogether, but can be expected to appear in subsequent volumes.

The opening paper by Bondareff is primarily concerned with the microscopic pathology and cytology of neurones of different ages. Only a short paragraph is devoted to the neurophysiological aspects of ageing processes in the central nervous system, and indicates how much less is known about functional changes in the nervous system with age than about morphological changes. Generally, Bondareff finds little undisputed evidence that important and causal changes with age can be identified in the central nervous system.

The two contributions from Europe come from Rumania (Oeriu) and the U.S.S.R. (Medvedev) and deal with the roles of proteins and nucleic acids in ageing processes. Both take a very broad view of the scope of ageing studies and extend their surveys to the early stages of embryonic development. Medvedev, in particular, shows how much we now depend on advances in molecular biology to provide hypotheses and ways of looking at the ageing process, either in terms of the accumulation of transcription errors or of the 'noise' engendered by the unmasking of genes at predetermined and later ages.

Oeriu ranges even more widely in a catalogue-type of review providing information about changes with age in the tissue contents of protein, enzymes and vitamin co-enzymes and in amino-acid patterns. He believes that the accumulation of disulphide bonds inhibiting enzyme activity is important and illustrates in detail his experimental findings that cysteamine and folic acid can restore the biochemical balance towards the situation characteristic of younger ages.

The three other general reviews are by Casarett, Clark and Blumenthal and Berns. Casarett critically discusses the extent to which exposure to irradiation can mimic or accelerate natural ageing changes and, while finding differences between the two processes, believes that the similarities are sufficient for the irradiated animal to be a useful model system. He, too, puts forward a theory of ageing in which he sees both irradiation and natural ageing having their effects as a result of increasing connective tissue barriers between the circulation and the parenchymal cells.

Clark's contribution on genetics and ageing is, perhaps, the most readable of all. He emphasizes the importance of genetic factors, the opportunities for research which genetically controlled material provides and discusses the relevance of somatic mutation to ageing studies.

Blumenthal and Berns's topic is auto-immunity and they too are concerned with the importance of somatic mutations. Their discussion centres mainly around possible ways in which modifications in immunological reactivity may lead to the diseases of old age and attempts to bridge the gap between the concepts of natural and pathological old age.

The remaining articles are by Andrews on changes in nuclear morphology, a short informative note by Sinex on cross-linkages especially in collagen and elastin, and two by Björkerud and the editor, Strehler, on the isolation of lipofuscin granules from heart muscle and the chemical and enzymatic properties of the particles, and on the histochemistry and ultrastructure of age pigments. There is considerable new and detailed information here about techniques, biochemical findings and histochemical appearances together with speculations on the origins of the granules. One wonders, however, whether the likelihood that these granules are more than an epiphenomenon of ageing is sufficiently great to justify the allotment of about a fifth of the book's pages to this topic.

Most of the present-day views on the causes of ageing are aired somewhere in these reviews. The authors vary considerably in their approach to the problem of how to prepare an article for this type of book and some succeed better than others. Some degree of overlapping and a few trivial proof-reading failures occur. Not everyone will want to read straight through the volume, but anyone who delves into its pages is bound to come up with some fresh ideas and some new pieces of information.

In the past, reviewers of books on ageing have often begun by emphasizing the unpopularity and lack of scientific respectability of ageing studies. To be included in the *Advances* series can be taken as good evidence that the subject has at last arrived. But in addition to marking this event, an important thing about the book is that it makes one realize how amorphous and pervasive a subject ageing is and how dependent workers are on advances in other fields. More depressingly, it serves to show one how little real progress has been made in coming to grips with the main problems.

P. L. KROHN

## BIOLOGY OF RESPIRATION

The Biology of Respiration

By Sir Victor Negus. Pp. xi+228. (Edinburgh and London: E. and S. Livingstone, Ltd., 1965.) 60s. net.

THE *Biology of Respiration* by Sir Victor Negus is a disappointing book on a number of counts. In the first place, the title promises considerably more than the contents offer. I anticipated that this would be August Krogh brought up to date, incorporating the mass of work on the comparative physiology of respiration carried out since the publication of his classic in 1941. In fact, the contents are very much restricted in scope. About three-quarters of the text is concerned with the external apparatus of respiration and is clearly centred around the unique contributions of this distinguished oto-rhinolaryngologist. When he is on home ground, Sir Victor is superb without qualification, and this remarkable account of fastidious dissection of the upper airway systems of innumerable species, admirably illustrated, carefully, thoughtfully and crisply presented would, by itself, justify the purchase of the book. This part of the book is marred only by compression; for example, it might be thought that the complex air sac system of birds deserves more than half a page of text and the mechanics of pulmonary ventilation in mammals more than a brief mention.

However, there is more to respiration than the passage of air in and out of the upper respiratory tract, or of water over the gills of fish; the most serious criticism of the book is that there is little attempt to correlate anatomical adaptations with physiological function. Thus, for example, there is nothing on foetal respiration; in discussing diving mammals and birds, the discussion barely goes beyond the use of stopwatches, and the names Scholander and Irving are never mentioned. There is no mention of adaptations to altitude nor any discussion of the relation between respiratory gas exchange and the size and metabolism of mammals.

Instead of this, the author has inserted two highly compressed chapters on respiratory gas exchange and the neural control of respiration which apply only to man or common laboratory mammals. The latter chapter, in particular, provides a synopsis that is potentially misleading for the novice and irritatingly dogmatic for the professional.

Where space is at a premium, a statement such as "The effects of changes in arterial pH upon pulmonary ventilation do not, however, depend on the alteration of pH *per se*, but are determined by the extent to which the pH change is caused by or gives rise to coincident alterations in arterial PCO<sub>2</sub>," is not only ambiguous but positively misleading since no mention has been made of the medullary pH-sensitive chemoreceptors or of the role of the pH of the cerebro-spinal fluid.

The bibliography contains 98 references of which only about a half are primary sources.

There is a very real need for a comprehensive book with this title, a book which would gather together the work done so far and emphasize where the tracts of ignorance lie; Schmidt-Neilsen's recent *Physiology of the Desert Animal* is an admirable model. It might require a reincarnated John Hunter, to whom Sir Victor is clearly much indebted, to do justice to such a labour. In his absence, Sir Victor and Messrs. E. and S. Livingstone, Ltd., might consider expanding this book with Sir Victor's unique contribution as the nucleus. Zoologists and respiratory physiologists would then be much in their debt.

M. J. PURVES

## THE PROTURA

### The Protura

A Revision of the Species of the World with Keys for Determination. By Prof. S. L. Tuxen. (*Actualités Scientifiques et Industrielles*, No. 1311.) Pp. 360. (Paris: Hermann, 1964.) 54 francs.

THE Protura, a group of small Arthropods usually placed for convenience with the Insecta, were not recognized at all until 1907 when Silvestri described the order and the first species; even now there are fewer than 150 known species. The original descriptions, with a few exceptions, are inadequate, resulting in names being applied to different species by different workers and in the formation of many synonyms. The only remedy for this is to interpret conclusively all the specific names by examining the type material—designating lectotypes where necessary and erecting neotypes where the types are lost. This, together with a re-assessment of taxonomic characters, has been done by Prof. Tuxen in *The Protura: a Revision of the Species of the World with Keys for Determination*.

In this, 48 pages are devoted to morphology, partly based on original work by Prof. Tuxen, with emphasis on the characters used in the classification. Post-embryonal development is dealt with in three pages, while techniques of collecting, examination and preservation are outlined in one. A list is provided of references to ecology and distribution (arranged geographically) together with a systematic list of all the known names, ten pages of

references to the literature, and indexes to names and subjects. The rest and greater part of the book contains the systematic discussion, keys, figures and descriptions of the species, including discussion of the intra-specific variation of some of the characters; all are clearly and conveniently presented.

Thus, for the first time a critical re-assessment of all the morphological and systematic information about the Protura is contained in one volume and it should now be possible to determine Protura material correctly. However, in using the keys it becomes apparent that for identification the specimens must be in good condition and some familiarity with the order is necessary, the arrangements of the sensillae and setae of the foretarsus being especially difficult to resolve; in this respect it is unfortunate that some of the figures of the foretarsus, as mentioned in the preface, have been so much reduced. One other criticism that might be made is the number of genera which have been used for the relatively small number of species, but in Prof. Tuxen's opinion this is a necessary, perhaps only temporary, step to survey a group in which relationships and evolutionary lines are difficult to assess.

It is hoped that this work with its high standards of taxonomy will induce similar standards in the work of subsequent taxonomists of the group and encourage the collection of information on the biology and ecology of the Protura. Further, their distribution may prove to be of considerable zoogeographical interest.

THELMA CLAY

## MORE ABOUT COCONUTS

### Coconuts

By Dr. Reginald Child. (*Tropical Agriculture Series*.) Pp. vii+216+25 plates. (London: Longmans, Green and Co., Ltd., 1964.) 42s. 6d. net.

IT is often surprising to observe, in quite different parts of the world, that coconuts are so badly grown, or so indifferently maintained. Of course, it can be appreciated that, with rising costs of labour, the crop is probably one on which only marginal sums can be spent. That, at least, is the general assumption. However, in these days of scientific agriculture, from the application of which other major tropical crops have certainly profited, it might reasonably be expected that more could be done to improve this important and valuable crop. The potentialities are there: very considerable areas could be utilized, in simple ways, for the cultivation of the coconut, if only . . . ! In fact, there are regions where scientific agronomy is being practised to advantage.

Accordingly, the handy volume prepared by Dr. R. Child, formerly director of the Coconut Research Institute of Ceylon, and produced as one of the *Tropical Agricultural Series*, under the editorship of Mr. D. Rhind, is to be welcomed. (The last considerable monograph on this crop, *The Coconut Palm*, was prepared for the Indian Central Coconut Committee by Dr. K. P. V. Menon and Dr. K. M. Pandalai several years ago.) A further circumstance which adds to the value of the new volume is that the relevant research and technical literature, which is often not too readily accessible to the grower who does not happen to be closely associated with a scientific department or institution, is presented in condensed form. Indeed, in a special chapter, the author has been at pains to inform his readers on this point, for, as with other pan-tropical crops, the literature tends to be somewhat scanty and widely scattered. In fact, various journals and reports are now being produced regularly in Ceylon, the Philippines, India, Malaya, Fiji, etc., and in Paris for regions within the French economy. There has also been recognition of the need for co-operative scientific work in tackling the problems of cultivation and protection—and

they are considerable—of this valuable and potentially extensible crop.

Dr. Child has dealt, in short, informative and readable chapters, with the history and botany of the crop, its cultural requirements, the importance of selection and breeding in the establishment of plantations, and with the many other problems of care, maintenance, fertilizing, processing and products. Pests, of quite diverse kinds, from insects to crabs, and diseases, which are often difficult to diagnose, which afflict the coconut, are described and illustrated. Indeed, a very considerable amount of information has been condensed into some two hundred odd pages. The book is helpfully illustrated by line drawings in the text and by photographic plates of good quality.

Especially in these days of expensive technical books, this volume impresses me as being really good value, both for the practical grower and the research reader. Nor is the coconut without its mythology and mystery: let the curious reader find out for himself about 'coconut pearls' to which a short appendix is devoted.

C. W. WARDLAW

## MECHANISMS OF HORMONE ACTION

Actions of Hormones on Molecular Processes

Edited by Gerald Litwack and David Kritchevsky. Pp. xi+588. (New York and London: John Wiley and Sons, Inc., 1964.) 128s.

THE editors are to be congratulated on their idea of collecting nineteen articles relating to the mechanism of hormone action at the molecular level, for interest in this subject has grown rapidly in recent years. The coverage of subjects is, naturally, not comprehensive, but their selection is a good one. The hormonal influence on transport across cell membranes is discussed by Riggs, and there then follow four articles on various aspects of thyroid hormone action. Gonadotrophins and the sex hormones are discussed in four chapters, while corticosteroids, insulin and the catecholamines merit three articles each. There is also a discussion of gastric and the duodenal hormones. It is of interest that in many of the articles the emphasis is on hormonal action mediated via messenger RNA synthesis.

The articles are excellently written accounts, serving as good reviews of the literature, and many of the authors have taken advantage of the opportunity offered by the editors to speculate. Such personal views are often useful if only in promoting thought and experiment to counter an unpopular opinion. The book is clearly printed, the figures are admirably clear, the type is pleasing to the eye, the index is useful and appears to be both comprehensively and sensibly compiled.

But, and this is an important qualification, there was obviously a delay of about two years between the time when most of the articles were written and that when the book was published. Such a delay may be of limited consequence in some subjects but in rapidly developing fields—and this book was clearly envisaged as being in one—a delay of this length can be disastrous. One of the contributors has added an addendum to his thoughtful, elegant and comprehensive chapter (which clearly took a great deal of work and thought to write), in which he says that during the delay between writing the chapter and reading the proofs (18 months) it had become a period piece and that to attempt to bring it up to date would entail expensive revision. He is perhaps a little too hard on himself, but it is difficult not to sympathize. When asked to contribute a review article, many scientists feel an obligation to do so in order to tie together the diffuse and voluminous literature on their subject or to put their own view. No doubt, too, we respond to the implied flattery of the invitation. A review article,

especially one which is a thoughtful selection and discussion of relevant papers, requires a great deal of hard work to write, and it is a great pity that the hard work should be, to an extent, wasted by delays in publication.

A. KORMER

## MICHAEL FARADAY

Michael Faraday

By L. Pearce Williams. Pp. xvi+531. (London: Chapman and Hall, Ltd., 1965.) 70s.

IN his warm and human biography of Michael Faraday, Prof. Williams has traced Faraday's development as a man and a scientist. After describing Faraday's early days, he has chapters on his education as a chemist and philosopher, and on the "Fallow Years" between 1820 and 1830 when he gave up his researches in order to devote himself to the interests of the Royal Institution, raising it in popular esteem and strengthening its financial position. Then came the great years of the discovery of electromagnetic induction, and the author describes the development and clarification of Faraday's conceptions in three chapters on "The Nature of Electricity".

The chapter on "Faraday in the World" is of particular interest because it contains an account of Faraday's study of the art of lecturing. He had as a first model Humphry Davy, a master of that art. "Faraday had been preparing himself to replace Davy for a decade and it was his ability to reach a lay audience which was, over the course of some thirty-seven years, to give the Royal Institution that popularity and financial security it had so long needed." Faraday's advice to a lecturer about the importance of speaking his discourse, not reading it, reveals his combination of courtesy and firmness in a delightful way, "as we are sure that you would do it better the less you read, so I venture to express a hope that you will not read more than you may find necessary for your own convenience".

Another fascinating chapter deals with the origin of the field theory. Prof. Williams enables us to follow Faraday's lines of thought by the frequent well-chosen extracts from his papers and diary. There is, however, a blemish in this chapter which ought to be corrected in a further edition. A series of figures on p. 439 *et seq.*, which purport to illustrate Faraday's ideas on the distortion of a magnetic field by paramagnetic and diamagnetic bodies, are false in that they represent lines of force with physically impossible contours. Faraday's original rough sketches (Experiment 10,832, April 1850, in his *Diary*) and the finished drawings (2,807, October 1850, in "Experimental Researches in Electricity") are beautifully executed even though Faraday had to extrapolate in exaggerating the effect of a diamagnetic. His intuition led him to their right form, although he had no mathematics. The pictures in the book, on the other hand, show the lines of force which disobey the laws Faraday had so brilliantly established. Then again, on p. 393, in referring to "the setting of his glass across the magnetic lines of force", the author appears to suggest that a diamagnetic rod sets itself at right angles to the force in a uniform magnetic field, whereas, of course, it sets itself in a parallel direction like a paramagnetic, a phenomenon so elegantly explained by Faraday's conception of a field as opposed to that of induced poles. The familiar experiment in which a bismuth rod sets itself across the magnetic gap is explained by the ends of the rod being drawn to places where the field is weaker.

A number of books have been written about Faraday, but in the present case the author must have consulted more of the original sources than any previous biographer, and the result is a very complete and scholarly record, which is a notable addition to our knowledge of nineteenth-century science.

W. L. BRAGG

## HEADS OR TAILS

By DR. R. T. GREEN

Department of Psychology, University College, London

IN the social sciences, recourse is often made to non-parametric or distribution-free tests because the data are not amenable to the more traditional statistical procedures. Of these, the binomial or sign test is one of the earliest, simplest and most flexible. It can be applied to any binary series of the heads and tails variety to test the null hypothesis that the coin is true; that is, that the two outcomes have an equal probability of occurrence. Although the mathematics is straightforward, there has been a measure of disagreement over the epistemology involved. Since the test can be applied only to two-category outcomes, what is to be done when the coin lands on its edge (an indeterminate outcome) or is knocked off the table before we note its face (an unobserved outcome)? With a coin this type of outcome is unusual and the consequences trivial. In the social sciences the neutral category is apt to occur more often and the problem cannot be ignored.

For example, let us take a simple experiment in perception. We ask our subject to inspect a curved line presented in a manner to exclude all other structured stimuli. After five minutes we remove the curved line, replace it with a straight one, and ask the subject if the new stimulus is straight or curved and, if curved, in which direction. Thus, the subject is offered a three-category response. On the null hypothesis that the inspection of a curved line for five minutes will not systematically bias the perception of a straight line viewed immediately afterwards we would predict that he will not favour either direction of curvature and is just as likely to report the one as the other, regardless of how likely he is to choose the middle category of response. That is to say, if we run 100 subjects and 90 of them report the second line as straight we would expect the other 10 to split equally between the remaining two categories. Suppose, however, all 10 respond in the same direction. Are we then entitled to reject the null hypothesis at the 0.002 level of confidence on the grounds that this is the likelihood of getting 10 heads or 10 tails in a row? There are some statisticians who would challenge such a procedure and a second example is perhaps necessary to sharpen the issue still further.

Let us suppose we are engaged in an investigation of political imagery and that we are comparing the attitudes of working-class Conservatives with those of working-class Labour supporters. We have set up a hypothesis that the Conservatives will choose as an ideal Prime Minister someone who makes a good father figure, while the Labour supporters will be less inclined to make such a choice. This time we are careful to design the experiment so that each subject can be unequivocally designated as a positive or negative instance. The null hypothesis, of course, is that the choices of the two groups will not differ significantly in this respect. Our definition of working-class is a standard one based on occupational level, but not being altogether naïve in such matters, we take the trouble—after obtaining the imagery scores—to discover whether or not the respondent regards himself as working-class. To our chagrin, a number of subjects who sweep the roads, deliver milk, and mix cement, yield evidence that they see themselves as members of the middle class. We discard them on the grounds that we have no predictions to make concerning the psychodynamics of such difficult people. Are we justified in

treating the remainder of the sample as representative of the universe we are interested in and conducting a  $2 \times 2$  contingency analysis of the positive and negative cases for the two political affiliations? Note, we could in principle have saved ourselves the trouble of measuring the attitudes of these odd people we eventually discard simply by discovering their class attitudes at the start. It just so happens that we prefer not to follow this procedure in the interests of good experimental design.

Returning to the coin analogy, what we wish to do is test the null hypothesis that two coins are equally biased without wishing to assume that both are true. Again, in order to carry out the desired statistical test it is necessary to discard the unobserved and indeterminate outcomes. Since this is just a more complicated version of the first problem of testing the trueness of a single coin, we shall consider the arguments relating to the simpler case first.

The simplest and the most attractive solution is to discard the neutral cases no matter how frequently they occur, as had been suggested by Dixon and Massey<sup>1</sup> and Siegel<sup>2</sup> in a manner which is casual enough to imply that no difficulties are involved. Objections have been raised against this procedure, however, and if we are to use it we must demonstrate that we do not thereby invalidate the basic requirements for applying this test. Putter<sup>3</sup> has shown how the way we choose to deal with the neutral category affects the exact power and asymptotic efficiency of the test. What does not appear to have been done is to consider the epistemology lying behind the choice of one procedure or another when applying the sign test in particular instances. For once, the most attractive procedure turns out to be the most logical, as the following three arguments demonstrate.

(1) If we were kept in ignorance of the outcome of, say, half the total number of throws we would be obliged to carry out our analysis on the remaining throws of known outcome. Any sample of throws we take is of necessity, and by definition, only a small part of an infinite universe of possible throws. The unobserved throws not included in the sample may all be indeterminate and land on their edge for all we know, but this does not and cannot affect the treatment of the sample we actually have. This is the essence of the binomial test. We define our sample, and the test says whether or not the procedure producing that sample is biased. If we define our sample as that which specifically excludes unobserved or indeterminate outcomes, then the test cannot refer to any events outside our sample as defined. The distinction between unobserved and indeterminate outcomes is of no logical significance in this context.

(2) If it is argued that to be conservative we should allocate all indeterminate outcomes to the direction favouring the null hypothesis, this can be shown to lead to an absurdity. It sounds reasonable only if we confine this procedure to samples in which the coin lands on its edge relatively infrequently. A thick coin makes nonsense of the argument, as it could reverse a significant bias in one direction and make it appear as an even more significant bias in the other. For example, if on eight consecutive tosses having an observed determinate outcome the coin comes up heads every time (it is a double-headed coin if one wishes) we would reject the null hypothesis at the 1 per cent level of confidence, ignoring the indetermin-

inate throws when it lands on its edge. If it is a very thick coin and there have in fact been, say, one hundred indeterminate throws, and we allocate these against the emerging bias, we are obliged to reject the null hypothesis at a far higher level of confidence, and conclude that the coin is biased in the opposite direction from that in which it really is biased. To split the indeterminate outcomes in the proportion of the determinate outcomes, as is sometimes recommended, only helps to undermine the null hypothesis. The only procedure that is genuinely conservative is to split the indeterminate outcomes 50:50, with an odd member going to the smaller total of determinate outcomes.

(3) The fallacy of including the indeterminate outcomes in the analysis at all is best seen by considering the properties of thick biased coins. Let us take a coin which is tapered across its edge as if it were a truncated cone. Such a coin is patently prone to bias, although the degree and direction of bias will be a complex function of the angle and thickness of the edge and the sizes of its faces, apart from its elastic properties and the nature of the surface on which it lands. Without getting involved in the dynamics and geometry of the process, it would obviously be quite straightforward in principle to manufacture such a coin with any degree of bias we chose.

Let us suppose that we produce a coin with a 60:40 bias, in the sense that out of one hundred observed and determinate throws it will on average reflect this bias. Now the number of times we actually have to toss this coin in order to arrive at one hundred observed determinate outcomes will be a function of the way the coin is made. It could be made to produce one hundred determinate outcomes in 102 throws or in 200, but the question as to the direction and degree of bias with respect to the two faces can be settled by reference only to the observed determinate outcomes.

In effect we are dealing with a three-faced die and confining our interest to the relative probabilities of occurrence of only two of its faces. The third outcome is of no relevance to the null hypothesis that the two faces in which we are interested have an equal probability of appearing. The only relevance that the third outcome has is with regard to the amount of work we have to do in order to confirm or refute this null hypothesis. A thick coin has to be tossed a greater number of times in order to obtain a sufficient number of determinate outcomes with which to test the null hypothesis that is of interest to us, whereas a thin coin involves us in far less wasted effort obtaining outcomes not falling into the sample as defined.

These arguments may be summarized by considering a true roulette wheel of 100 pockets, any of which may be red, black or white. If we confine ourselves to asking whether there is an equal number of red and black pockets, then any trials in which the ball comes to rest in a white pocket must be ignored. According to the definition of the sample universe in which we are interested these trials are not trials at all. So far as the mathematics is concerned, it makes no difference whether there are 49 red, 49 black and 2 white pockets, or one red, one black and 98 white pockets. The null hypothesis with regard to red and black can be tested only by reference to those trials on which the ball comes to rest in a black or red pocket. The fact that in order to get a sample of 100 trials we have to spin the wheel a little more than a hundred times in the first case, and something like 5,000 in the second, is entirely irrelevant to the legitimacy or otherwise of the mathematics. If there are in fact twice as many red as black pockets we shall detect this degree of bias in just as many trials, but for a very different number of spins, whether there are two red and one black pocket, or 60 red and 30 black pockets.

The same arguments hold if someone upsets the wheel, or switches out the light and removes the ball, in a

random sequence during the course of our experiment. Our sample size is thereby reduced, and we have to make that many more spins to restore it. But, provided that the process is random, then the mathematics of the binomial theorem still apply to those events that we define as belonging to the sample universe. That is, they are determinate and observed. The indeterminate outcomes we have elected not to take an interest in, and the unobservable and unobserved we may not include in our analysis. If there is some systematic bias in the way that the light is switched out, or the wheel is upset, then this process must be investigated in some other way. The null hypothesis we choose to test makes the implicit assumption that the indeterminate and unobserved outcomes do not in fact suffer from such a systematic bias. The possibility that such a bias does exist is always with us, but it holds just as much for the tosses or spins that are unobserved because we have not made them as for those that are indeterminate because the coin lands on its edge, or unobserved because someone switches out the light.

It is not difficult to see that these same arguments hold if we are interested in testing the null hypothesis that two roulette wheels carry red and white pockets in the same proportions, regardless of how many pockets either has *in toto*, or what proportion of the pockets is white. The interesting question is why there would appear to be anything to argue about over this matter of discarding the neutral cases. Possibly the answer is to be found in one of the chestnuts that statisticians are fond of using to show how easy it is for common sense to lead our reasoning astray. The conundrum runs like this: "A woman has two children. One of them is a boy. What are the odds that the other is also a boy?" (It is assumed that there are an equal number of boys and girls in the universe under consideration, and there is no Markov chaining.) The correct, and slightly surprising, answer is 2:1. If we are surprised this is because we have been addressing ourselves to the wrong universe. The common error is to assume that we are dealing with the entire universe of women with two children, in which case the answer would obviously be 'evens'. In fact part of this universe, the quarter containing women with two daughters, has specifically been excluded, and we are left to deal with a universe in which 2/3 fall into a boy-and-girl category and 1/3 in a two-boy category. Had we been told: "A woman has two children. The first born is a boy. What are the odds that the other is also a boy?", then the answer would indeed be 'evens', because another part of the women-with-two-children universe has been excluded, and the remaining universe under consideration contains boy-then-girl and boy-then-boy in equal proportions.

The social scientist, in setting up his null hypothesis, is entitled to address himself to whatever universe he elects to investigate. If he wishes to exclude from his analysis subjects who report straight lines as straight, or working-class respondents who see themselves as middle class, then he is perfectly entitled to do so. His conclusions will, of course, be limited in that they will refer only to the universe to which he addresses himself, and he will not be able to make statistical statements about respondents lying outside his chosen universe, but there is nothing wrong in this. Provided he recognizes the limitations he has imposed on himself then he cannot be taken to task for using the sign test or 2x2 contingency analysis on his remaining data.

Reverting to the first example, if he wishes to confine his interests to those subjects who report a straight line as other than straight, and if 10 such subjects all report the straight line to be curved in the opposite direction to the one they inspected for five minutes, then he is entitled to reject that particular null hypothesis at the 0.002 level of confidence. The sort of statement he would end up making after running his 100 subjects would be

that: "Most people do not seem to be affected by the prior inspection of a curved line, but if they fall into the minority that is affected then it is highly probable that they will be affected in the particular direction revealed by the experiment".

With the second example the same arguments hold. Provided the experimenter confines his conclusions to working-class respondents who see themselves as working-class, he is quite within his rights to confine his analysis to these respondents. Nor does it matter whether he discards the 'neutral' cases before or after making his imagery assessments. This is just a question of administrative convenience, and is not on a par with deciding what to do with the results after having had a look at them and discovering that the 'neutral' cases are swamping the data.

The procedure is suspect only if it is *post hoc*. Statisticians have good cause to be wary of the experimenter who decides what tests he will make after having collected and inspected his data. If there are a hundred possible comparisons that could be made, then, on a purely chance basis, five of these comparisons will appear to be 'significant' at the 5 per cent level of confidence, and it would be picayune, to say the least, to seize on these as satisfactory evidence for rejecting some handy *ad hoc* hypothesis. See Cochran and Cox<sup>3</sup>, Snedecor<sup>4</sup> and Tippett<sup>5</sup>. (This is not to say that all statistics are necessarily invalid when used *post hoc*.)

Similar considerations apply to the experimenter who neglects to specify the universe in which he is interested before collecting his data. If he fails to foresee the possible consequences of including the neutral category and decides to exclude subjects who 'land on their edge', so to speak, only after inspecting his data, then he lays himself open to the same sort of suspicion as the experimenter who neglects to specify which groups he intends to compare. By tampering *post hoc* with his universe in various ingenious ways he could 'prove' that blue-eyed men are taller than brown-eyed men, or vice versa, simply

by adjusting his universe to exclude the awkward instances.

Perhaps it would not be too misleading to assert that the issues at stake in the real world, when we come to assess the value of an experimenter's work and the legitimacy of the statistics he uses, are not so much mathematical or even epistemological, but fundamentally psychological. A man who is known to have a theoretical system which he defends against all attacks at any cost must expect to have his procedures, experimental and statistical, examined with more care, simply because of his known propensity to shape the facts to fit into his paranoid delusional system. On the other hand, the competent experimenter with no theoretical axe to grind, who has shown himself content to shape his theories to the facts, or even abandon his theories if the facts demand it, earns our trust and respect. Because he is not irrevocably committed to an entrenched theoretical position, but is committed to 'discovering and facing up to the facts, we are more inclined to trust both his data and his treatment of them. Where the experimenter places his emotional investment, in a theory or the facts, is a highly relevant piece of information. Every scientific worker acquires a reputation somewhere along this dimension, and other workers habitually use this knowledge to weigh the value of his contribution. This may not sound much like scientific method as it is described in the text-books but, as has been observed before, whoever uses scientific method it is certainly not the scientist.

I thank Dr. A. R. Jonckheere for his advice.

## CORAL REEFS, ATOLLS AND GUYOTS

By DR. R. SILVESTER

University of Western Australia, Perth

THE problem of coral reefs and atolls to-day is not so much a lack of information but perhaps a new approach in the interpretation of existing observations. Recent deep borings into barriers and reefs have increased knowledge greatly, but the new data do not appear to be consistent with existing hypotheses on reef origin. A new explanation is presented here which emphasizes the role of the predominant swell and the consequences to be expected when a massive structure, sitting on a saturated sedimentary foundation, suffers continual vibration. This hypothesis appears to cover adequately the existing knowledge of coral formations and points out the likely discoveries when further holes are drilled across an atoll complex. The major differences between guyots and atolls are accounted for in terms of subsidence resulting from wave action. The explanations presented do not invoke sea-level changes. The implications of this are noted.

Coral reefs in general and atolls in particular have intrigued geologists and lay persons alike, either through personal observation or through the literature published about them. They have been the subject of some lengthy treatises, of which those by Davis<sup>1</sup> and Wiens<sup>2</sup> are the most comprehensive. In spite of this concentrated attention since the middle of the nineteenth century, the

mode of origin of atolls in particular remains somewhat of a mystery. Gullcher<sup>3</sup> has been led to remark: "Coral reefs form one of the most complex questions in geomorphology".

Coral reefs can be established and maintained under a wide variety of conditions, due to the large number of species available; but optimal growth of the most prolific types requires that the temperature, depth, turbidity and salinity of the water be within certain limits. Temperature controls the geographic distribution of coral and depth determines the specific sites for reefs, mainly through its control of light intensity. Salinity requirements are readily met in the oceans and it is only by the occurrence of fresh water, as from river mouths, that coral growth could be impeded.

Turbidity can be a controlling influence by its reduction of sunlight in general and by the settlement of suspended particles on the reef structure, or its allied plant life, with the consequent reduction in photosynthesis. This factor could assume importance during the early stages of reef development, when the majority of the reef is within the zone of particle suspension. It is apparent, therefore, that the greater the wave agitation, or the finer the bed material, the deeper the platform required for coral development. In fact, conditions could be envisaged

where the combination of wave action and silty soil might require such great depths before turbidity were reduced that the light intensity would be insufficient for the establishment of a colony. This indicates that mud could serve as a foundation only in zones of little or no wave action.

Rock, on the other hand, when also exposed to persistent wave action, could also prove an unlikely site for coral development. This is because the waves, reflected from the relatively steep slopes, develop into standing oscillations or clapoti, the high water velocities of which would tend to wash young colonies away. But even where a reef survives this ordeal, the wave forces imposed on the mature structure would most likely be too great for the relatively weak contact it has with the rock face. This attachment consists mainly of a cementing action of calcium carbonate which would not extend laterally in proportion to the horizontal development of the reef at the higher levels. Sooner or later the whole structure would be torn from the face and be pounded to pieces by the waves.

Thus, for areas where wave incidence is high, the most likely foundation material will be sand or some coarser sediment. This can be accreted or eroded in quite shallow depths with minimal turbidity, so that platforms within the range for coral colonization (namely, 35–40 m) can readily be provided in open ocean conditions. The fragmented material of volcanic mounds in a marine situation would appear to satisfy the requirements for suitable coral reef support.

#### Theories of Origin

Hoffmeister and Ladd<sup>4</sup> have pointed out that theories concerning barrier reefs and atolls may be divided into two main classifications, namely: (a) those invoking a change in sea-level relative to the foundations, and (b) those based on a static situation.

**Changing levels.** Darwin<sup>5</sup> proposed that fringing reefs were established around the edge of volcanoes which had emerged from the sea. When these mounds afterwards subsided the coral continued to grow until a stage was reached where the foundation was some hundreds or thousands of feet below sea-level. Dana<sup>6</sup> and Davis<sup>7</sup> supported this thesis strongly, contending that the valleys and embayments, formed on the existing volcanic islands, proved the effectiveness of sub-aerial erosion. Semper<sup>8</sup> submitted that ocean currents channelled the rising mass of a volcanic island. This had also been considered and rejected by Darwin.

Daly published many articles; but elucidated his thesis fully in 1915 (ref. 8), which proposed glacial control of sea-level. Accepting prior reef formation, he contended that the lowering of sea-level exposed many of the reefs, which afterwards died. Wave action disposed of the coral and then eroded the volcanoes to the water line, after which the sea rose 35–40 fathoms to give the present uniform depth in the atoll lagoons. This theory has received much criticism by Davis<sup>7</sup>, Kuenen<sup>9</sup> and Shepard<sup>10</sup>. A similar hypothesis was published by Vaughan<sup>11</sup>, except that initial colonization of platforms was envisaged during a low stand of sea-level, thus obviating Daly's required destruction of the atolls.

Kuenen<sup>9,12,13</sup> has attempted to combine the merits of the subsidence and glacial theories. Although he is strongly influenced by the former, he introduces eustatism as a necessity from other fields of evidence. He is not supported strongly in this respect; for example, Shepard<sup>10</sup> has been led to state: "It is difficult to assess accurately the importance of glacial control of sea-levels in the development of the atolls".

Stearns<sup>14</sup> proposed that anticlines, either rising or stationary, could be the major repositories for coral reefs. In other areas isostatic lowering could account for the great depth of atoll foundations. In more recent times, he contended, eustatism has assumed greater importance.

Fig. 1. Section of atoll as proposed by Menard and Ladd<sup>14</sup>

**Static levels.** Tyerman and Bennett<sup>15</sup> considered that volcanoes had been bevelled by tides until the reefs had risen to protect them. In many cases the islands had disappeared before this protection was afforded them. Rein<sup>16</sup> thought that organic debris could have accumulated on the submarine volcanoes which had not reached depths for coral colonization. Murray<sup>17</sup> extended Rein's hypothesis to include dissolving of the interior as the reef extended laterally, ostensibly to account for the lagoon. Murray also proposed that platforms could be produced by wave abrasion.

Wharton<sup>18</sup>, who had surveyed many atolls, was impressed with the limited depth of the lagoons in spite of the steep exterior slopes of the foundations. For him this did not comply with a concept of subsidence so he submitted an explanation<sup>19</sup> of wave abrasion, suggesting 30–40 fathoms as the general limit of wave power for fairly friable material. Davis<sup>7</sup> was very critical of these views, but an analysis of his arguments illustrates strong prejudices.

Agassiz<sup>20,21</sup> suggested that the platforms beneath barrier reefs were produced by wave action. He believed that lagoons could still be excavated after the reef had partially formed due to the topping of the waves. Hoffmeister and Ladd<sup>4</sup> have submitted an antecedent platform theory, having earlier attacked both the subsidence theory<sup>22</sup> and the glacial theory of Daly<sup>23</sup>. These platforms were purported to have accrued from erosion, deposition, volcanic eruption or earth movements. Once they existed at suitable depth and in an appropriate biological environment, these shoals could foster coral growth, so that rise in sea-level "is not essential for the formation of a flourishing barrier or atoll". Ladd<sup>4</sup> has recently been associated with a hypothesis that shallow water limestones have accumulated on ancient volcanic caps which have necessarily subsided under the load. A diagram is included in this reference showing a limestone cap a mile in thickness on which the reef is located (Fig. 1). Whence this vast volume of limestone was derived is not stated, but it should be realized that in the case of Eniwetok Atoll, which is some 20 miles in diameter, the volume of this disk would be in the order of 1,200 cubic miles.

Hass<sup>24</sup> has submitted that a reef subsides like a piece of cake after its central zone has become extinct through lack of nutrients and sediment asphyxiation. This view is based on the apparently false premise that "the depth of the lagoons seemed to bear a direct relationship to the size of the atoll".

From all these divergent opinions the writers of textbooks and monographs have been unable to perceive a unifying theme. Guilhaud<sup>25</sup> noted the lack of attention to wave forces: "The exact effects of swell and currents remain to be determined. These factors are undoubtedly important, but how do they fit in with eustatic oscillations and subsidence?" Wiens<sup>26</sup> concludes: "From the preceding discussion it can be seen that answers to the origin and evolution of coral reefs and atolls still are inconclusive in many respects".

#### New Theory of the Origin of Atolls

Consider a volcano which has just emerged from the sea and has become dormant or extinct. It is likely to be

circular in plan with a crater depression at its centre. The following analysis, however, does not depend on this latter assumption. As the lava was discharged at or near the surface of the sea it would have been cindered, and that ejected through the air likewise would have been fragmented, forming tephra. The speed and duration of the volcanism would determine the volume and distribution of debris and also the volume of the hard core, which had cooled more slowly.

Ocean swell would immediately attack this friable surface, aided and abetted by any local wave system. This erosion has been shown, from recent cases of volcanic action<sup>24</sup>, to be extremely rapid, especially where swell is involved, rather than local storm sequences which are relatively infrequent. Once a platform of reasonable size had formed, both through erosion and deposition, the waves would break further from the beach so formed and normal shoreline processes would ensue<sup>25</sup>.

The width and type of apron would vary around the periphery of the volcanic island, the orientation being determined by the swell waves, which arrive persistently from one direction<sup>26</sup>. As seen in Fig. 2a, the bench on the swellward boundary would be erosional, tapering at the sides and turning to deposition on the leeward margin. A sloping beach profile would soon be established on the zone receiving the brunt of the swell waves. It is on the seaward edge of this ledge that the optimum depth for coral colonization will be reached first. As noted previously, this implies reduction of turbidity as much as appropriate light and temperature conditions. Thus, even when similar depths are reached at the sides and to leeward the continued transmission of debris in these regions would preclude reef establishment.

**Initial reef.** On the swellward profile it is only the seaward edge that can provide a permanent footing, because inshore the steepening of the waves is still creating too much disturbance. A crescent-shaped reef will thus emerge as in Fig. 2b. In its infancy it will not influence the incoming swell, which will continue to erode and distribute the volcanic debris. When the reef reaches part way to the surface, it will induce wave-breaking, so that material could still be denuded between the reef and the island. The waves will diffract at the extremities and so enter this partially formed shadow zone; this will also occur when the reef is fully developed. As seen in Fig. 2c the opposing wave trains could create standing waves or clapotis, which produce excessive bed movement. These will, in association with waves breaking over the structure, continue the bevelling of the shoreward zones. It can be appreciated that any coral which had found a footing inside the marginal reef would have difficulty

in surviving the prolonged agitation of volcanic ash and tephra in this area.

The waves, diffracted by the reef and refracted by the shoal conditions (Fig. 2c), are still able to attack the island structure, the leading edge of which is thus forced back from the initial reef. No protective coral colonies can be established at the sides or leeward until all the erosion has occurred to a stage where turbidity is reduced to survival level. In the event of coarser than normal basaltic material becoming exposed to the waves, reefs could be established and so afford some protection. This would result in an almost-atoll, or even a volcanic island surrounded by a barrier reef.

There could well be several false starts to the initial reef since, at these early stages, large land-slides could ensue with concomitant turbidity of the surrounding sea. These could reduce and kill the existing colonies. The persistent swell, however, will cleanse the same region before all others, so that it again becomes the location for atoll genesis. At the sides and on the leeward face of the island the eroded material is deposited with very little compaction. Intermittent submarine slides could therefore be expected, which would have an adverse effect on any corals that may have survived these turbid conditions. In time, however, sediment movement would decline and the next site for coral would be the side margins (Fig. 2d). An important control is effected by the diffracting waves in the leeward region, which prevent reef formation until nearly all the volcanic mound has been reduced below sea-level, at least to the depth where sediment suspension is negligible.

As soon as the initial reef assumes a reasonable height above the bevelled mound, waves will be reflected with varying degrees of efficiency. Partial or complete clapotis will thus be established on the swellward side of the reef. Large oscillations of the water particles near the bed will result and mound material will be worked downhill or towards the side extremities of the reef. While the platform is deepened the sediment transported to the ends of the curved reef could form spits on which the colony could expand. It is at these points, where the reef is thickest, that the reef changes direction. Wiens<sup>4</sup> has accounted for this accretion by oceanic and lagoonal currents, but it is more likely to be from wave action.

**Reef extensions.** By the time the reef has extended itself to the sides of the volcanic island, the debris from wave abrasion of the initial reef will have started to arrive from the seaward face and be swept by the swell into the shadow zone of the leeward extremities. This promotes inward curvature of the reef as illustrated in Fig. 2e. Storm sequences may redistribute some of this spit material into the normally sheltered zone and so produce isolated mounds on which the reef could form. This results in a number of gaps or passes between coral patches in this zone. As these gaps decrease in size and number the flow of water through them, due to tidal changes or plain outflow of wave swash into the lagoon, increases to a point where colonization is precluded because of bed movement.

Through the processes described it is apparent that the atoll should assume an oval or U-shaped outline, with numerous passages in the zone sheltered from the persistent swell (Fig. 2f). This is confirmed by the published reports on the many hundreds of atolls existing in the Pacific Ocean and recorded on a statistical basis by Wiens<sup>4</sup>.

Should a crater have existed in the original island structure a stage will be reached where the wave erosion would cause a break-through of the sea into the depression. By this stage the reef development may be well advanced, but its survival as an atoll will hinge on the intensity of the disturbance during this crater inundation. If the volcano had a smouldering centre the contact of the sea-water would produce masses of steam and ash, which would be distributed over hundreds of square miles of

Fig. 2. Progressive development of an atoll from a volcanic mound

ocean. Even a cold crater would contain much fine ash which would be disturbed once waves entered the area. It is possible, therefore, that coral colonies of nearby and even distant atolls could be asphyxiated or retarded in growth.

The break-through of the crater edge is likely to take place on the swellward side, after which the crescent-shaped mound will continue to be denuded by subsequent swell (Fig. 2d). The crater will become the repository of much of the rim material. A significant change in the atoll development may occur at this stage due to a fresh pattern of accretion. The new zones of shallow water will influence the refraction pattern of the waves and so cause sediment transport which could distort the oval- or U-shape trend.

Should the reef be completely destroyed, the remaining part of the volcanic island will again be exposed to the full force of the oceanic swell. Its degradation may then be so swift that it might be bevelled below the survival limit for the coral, turning the mound into a flat-topped sea-mount or guyot. Such a result could also be produced without a crater catastrophe if the mound material had been exceptionally fine or friable throughout. It would then have been more easily eroded, in the style of a mud, and have been reduced to a depth greater than normal before turbidity was at a level suitable for coral subsistence. In the case of a reef having been established under these adverse circumstances, it could suffer more hazards from sub-aerial erosion and subsidence than when the volcanic debris was coarse. Any remnants of coral reef found on guyots should generally be found on the swellward end, since this is the zone where reef development would have commenced.

**Reef stabilization.** Returning now to the case of a thriving crescent-shaped coral colony on top of a partly bevelled volcanic cone, wave reflexion will increase as the reef builds up from the terrace bed. The higher the reef the more perfect the clapoti. As already mentioned, this standing-wave action agitates the bed more vigorously, with virtually infinite depth penetration, so that the seaward margin of the basaltic base is steepened and deepened. If this excavation were carried out too quickly the reef could well be undermined, causing it to topple towards the approaching swell. However, this is less likely if the reef has developed into a crescentic shape (Fig. 2b) and acts as a structural unit, for in this case the centre of gravity is well back from the reef edge.

But another, and more significant, effect of these clapoti is the continual pressure reversals applied to the seaward face of what is virtually a vertical wall. These produce vibrations which are transmitted to the foundation and assist in the settlement of the structure, the vertical load of which is constantly increasing from the addition of new reef. Since the coral on the seaward face is more prolific than that on the leeward side the extra weight provided is an eccentric load. From considerations of differential soil pressures it is apparent that the reef will tend to subside towards the oncoming swell.

The initial reef colony may not be very wide, but will slowly broaden out, mainly towards the open sea. The continual sinking, combined with its growing process, will ultimately form a wedge-shaped body, probably of a form as illustrated in Fig. 3a. The speed of settlement into the volcanic mound will vary greatly from barrier reef to atoll and between examples of either. It is dependent on the weight and height of the reef, the strength of the persistent swell and the nature of the foundation material. It will reduce with time since the soil resistance will increase while the wave forces remain ostensibly the same as those when the reef first reached the sea surface. There is an element of self-adjustment in this penetration process because the exposure to wave action is reduced as the reef disappears into the foundations, so moderating the vibrations which aid in this subsidence.

Fig. 3. a, Suggested penetration of coral wedge into a wave-bevelled mound; b, approximate proportions of Eniwetok atoll

In order to force its way into the footing the wedge-shaped reef (or any shaped reef for that matter) must displace some part of the foundation. Although part of this displacement will be in the form of soil compaction, the bulk will be provided by shear strain in the mound material. In this respect, the location of the reef near the edge of this conical foundation provides ideal penetration conditions. The outer slope is a zone of weak shear strength, and the inequality between it and the resisting forces available on the inner side causes the structure to deflect seawards as it is vibrated into the mound. This augments the turning tendency induced by the eccentric loading previously mentioned.

The saturated conditions under which this penetration is effected make comparisons with normal soil foundation problems rather tortuous. It appears reasonable to suggest, however, that the submerged condition of the sediment lowers its shear strength, due to the buoyant force of the water reducing its effective density from 2.65 to 1.45, for example. The pulsations, extending down the face of the wedge, produce pressure fluctuations in the pores of the soil which cause a reduction in its shear strength.

In time the reef should reach a stable depth at which the resistance balances the vertical load and the vibrational forces. It should be possible to determine by model experiments, or perhaps theoretical analysis, the optimum depth to which a reef of given dimensions would need to sink before it reached such stability or pseudo-stability. The rate of subsidence over time would be interesting to compute, if only qualitatively. Should it be uniform, and the age of atolls were considered, values in the order of one or two centimetres per annum would probably be sufficient to account for the thousand or so metres of penetration observed in some of the larger atolls.

The stabilizing effect of the crescentic outline has already been mentioned, but when the reef has more or less completed its encirclement of the disappearing or submarine volcanic mound, it is likely to act as a structural unit during settlement. The zone facing the predominant swell will be heavier and will be subjected to greater wave forces than the leeward section; it will, therefore, settle sooner and deeper. Such tilting of coral atolls might not be readily visible because slow subsidence is made good by further reef growth. A sense of proportion is provided by Fig. 3b, which gives approximate proportions for Eniwetok Atoll. It may be possible for the central axis of an atoll to act as a pivot so that the leeward region of the reef is lifted above its normal level. This would not be the case for isolated sections of reef on the sheltered periphery of the atoll, because they are not physically attached to the main body.

The root-type development described is necessary for the continual stability of the reef. If it did not exist the atolls could well be vibrated from the top of the volcanic

summit. Munk and Sargent<sup>11</sup> have stated: "Against the windward side of Bikini Atoll alone it is estimated that waves dissipate 500,000 horsepower, one-fourth the power generated at Hoover (Boulder) Dam". If the reef were just to sit on a flat slab, which in turn rested on the basaltic base, it would be only the frictional resistance between these three elements that could oppose the tremendous horizontal forces imposed in this pulsational manner.

Barrier reefs around islands or along continental margins will vary structurally from atolls only when the wave or sedimentary conditions are significantly different. The greater exposure of atolls to oceanic swell provides for deeper penetration than for barrier reefs. In the latter case, also, the more uniform development of the reef reduces the possibility of eccentric loading and the accompanying tilting of the structure. Even though it is not of the same order, the settlement of these reefs into the sedimentary shoal is an essential aspect of their stability.

This new thesis of atoll origin differs from those previously presented, both in the nature of the reef support and in the mechanism by which subsidence can be effected to great depths. The significance of the foundation conditions has been alluded to by other workers. For example, Ladd and Tracey<sup>12</sup> concluded that: "The origin of coral reefs will probably never be settled to the satisfaction of many investigators until a great deal more is learned about the foundations of existing reefs". Guilloher<sup>13</sup> also, in listing difficulties associated with atoll origin, has commented: "There are also the problems of the relative importance of corrosion and mechanical abrasion in the lowering of old reefs, and of the exact importance of this lowering".

#### Explanation of Specific Features

The theory of origin presented here should account for all features of coral atolls, the major ones being the lagoon floor and its boundary, lagoonal islets, the spur and groove system of the main reef, the seaward terrace and the steep submarine slopes of the volcanic mounds. Data on many of these features have been expanded in recent years by boreholes drilled into the margins of some atolls. Seismic surveys have also been undertaken to ascertain the foundation conditions for these coral structures.

**Lagoons.** The lagoons enclosed by reef, either partially or fully, differ as between the continental margin and the atoll situation. The former vary in depth from shore to reef since they are normal beach profiles partially encircled by a sand spit, on which the reef has established itself. Atolls, on the other hand, have lagoons which are more uniform in depth, ranging from 30 to 50 fathoms, with no correlation between this dimension and the width.

Around the edge of any atoll lagoon is a terrace of calcareous debris at about 10 fathoms depth. Much of this is fine sediment which is transported around the periphery by waves generated inside the lagoon by local winds. The floor of the lagoon is covered by calcareous mud and skeletal material containing calcite and aragonite. Hundreds of coral knolls rise from it to the surface, varying from pinnacle formations to massive patches of reef, which may cover many acres.

As seen in Fig. 3a, the continual outward tilting provides space on the lagoon side of the reef for debris to be deposited. This calcareous material becomes physically locked and cemented to the growing coral. Consequently it acts integrally with it and hence settles with it into the foundation. The boreholes so far drilled through the atolls have probably penetrated extensive depths of this detrital material, after passing through some growing reef and before reaching extinct original reef at a lower level.

As the coral progressively settles into the volcanic mound the supporting forces increase and the subsidence tends to zero. Horizontal growth becomes the main

feature of development, kept in check only by abrasion on the seaward face and deposition on the lagoonal face. Throughout this process the lagoon floor remains ostensibly the same. It may suffer slight lowering as material is worked into the void left by the outward tilting of the reef, but this is more than compensated for by the detrital products of carbonate precipitation, debris thrown over the main reef, and the coral knolls growing in the lagoon.

**Islets.** Islets are concentrated in certain sectors of the atoll periphery. They consist mainly of debris, as already mentioned above. Wiens<sup>14</sup> has graphed the incidence of these in 125 Pacific atolls and concluded that they were concentrated on the windward zone, although this was not clear from the diagrams. In this respect 'windward' must be differentiated from 'swellward', because the former controls the movement within the lagoon by the waves generated within it, while the latter determines the supply point of the bulk of the material through swell action. The various possible combinations of lagoon waves and persistent ocean swell are shown in Fig. 4, where it is seen that islets can vary widely in length and breadth. The occurrence of coral knolls on the lagoon may drastically affect the wave pattern within a lagoon and could therefore act as offshore breakwaters<sup>11,15</sup> to concentrate accretion behind them.

When an islet consists mainly of the residue of a volcanic island it is likely to be located at the leeward end of the atoll, away from the persistent swell. This would have been the last section to disappear, or to remain, when the final enclosure was being effected by the coral. Such islands would tend to be higher and more substantial than the normal islets which are constructed only to the 'reach' of the waves. It might be stressed that grouping many atolls together in a statistical averaging process, in order to assess the importance of certain factors in islet formation or location, serves little purpose unless the swell and local wind data are known for each. Even the general direction of oceanic swell may not suffice if an atoll is situated behind others so that only diffracted waves can reach it, necessarily from a changed direction.

**Spur and groove system.** This feature is most pronounced on the wave-exposed sections of atolls. The grooves run more or less radially across the reef from the seaward face to the lagoon. They extend down to the lagoon floor-level and vary in width from 2 to 12 ft. with a spacing of 10-50 ft. Between the grooves on the outer face the coral grows strongly, giving the impression of spurs protruding from a wall.

The reef structure as depicted in the present hypothesis is oval or U-shaped in plan and of a wedge section. It has penetrated a volcanic mound which has been bevelled flat to a depth of about 40 fathoms by the ocean swell. This penetration has extended hundreds or even thousands of feet with an inclination which has decreased with time.

Fig. 4. Effect of oceanic swell and local winds on islet distribution in atoll lagoons

giving a curved cross-section (Fig. 3a). However, this progressive enlargement of the periphery during subsidence would have caused cracking in the reef, similar to that occurring in a cup to which an outward force is applied. These cracks would be small initially, but once the zones of weakness were established they would be maintained. As each subsidence, either spasmodic or continual, occurs, the cracks widen. Even so, their contained angles are extremely small, for example, a 12-ft. wide groove in a 4,000-ft.-deep reef includes an angle of only  $0.25^\circ$ . These grooves are concentrated on the swellward region of the reef where subsidence and tilting are more pronounced. They do not appear to extend below the lagoon floor-level because debris is deposited in them from the lagoon and the seaward face of the reef.

**Seaward terrace.** On the seaward side of atoll reefs are near-horizontal terraces, which vary in width around the periphery and differ greatly from one atoll to the next. They can extend from a few yards to hundreds of yards in width at a depth of about 8 fathoms, which is slightly shallower than the lagoon itself. The terraces are more pronounced on the swellward margin and may, in fact, not exist in the leeward zone.

As mentioned previously, the outside of the volcanic mound is exposed to standing waves, resulting from wave reflexion on the reef, and so is steepened and deepened. But coral fragments of large dimensions accumulate on this sloping face and soon build up a calcareous apron to this basaltic base. This deposit will grow until a depth is reached at which the standing waves will not permit settlement and any new material is swept clear. Thus a terrace of cemented coral could extend from about 40 fathoms up to 10 fathoms approximately, which is the general level of this feature. The protection against wave erosion afforded by this calcareous apron is not available on the leeward sections of the atoll and hence continued agitation of the basaltic base results in very steep slopes to the mound in this area.

**Submarine slopes.** The slopes of the submarine mounds vary around the atoll, being some  $37^\circ$  on the swellward side and an average  $6^\circ$  steeper on the leeward faces. At some reef projections the steepest slopes are encountered, sometimes approaching  $68^\circ$ . These slopes are greater than those occurring around volcanic islands, and it is this observation that provides the clue regarding the importance of standing waves or clapoti, produced by reflexion of the swell from the reef face. These waves agitate the mound material to much greater depths than do the progressive waves approaching the beach profile of normal volcanic islands. This disturbance of the particles causes a downhill movement which results in a steeper grade beyond the limit of the seaward terrace. In the leeward zone of the reef clapoti are generated by the swell waves propagating around either side of the atoll (Fig. 2c). In this region, however, the terrace is slight or non-existent so that the reef itself acts as the fixed point from which the bed profile begins. The sea at these seaward faces of the reef is therefore extremely deep.

**Borehole data.** A number of holes have now been drilled into barrier reefs and atolls. The information has been summarized by Wiens<sup>1</sup> and Shepard<sup>10</sup>. The Great Barrier Reef of Australia exhibited a sandy base at about 400 ft. depth and a reef in Bermuda extended down 250-odd ft. Earlier borings on the atolls did not reach the basaltic base, but in 1952 two holes in opposite margins of Eniwetok atoll fortunately displayed it<sup>23,24</sup>.

One of the surprising aspects of the material extracted from the bores, either from the Funafuti<sup>25</sup>, Bikini<sup>26</sup> or the Eniwetok Atoll, was that shallow water Foraminifera was found in all of it, even from depths of about a thousand metres. This, however, confirms the contention that the reef itself and debris from it becomes buried at the depth of the lagoon floor and hence carries water organisms with it that inhabit this depth. In the bores drilled so far these

marine indicators have a distinctive lagoonal origin. The holes, it should be stated, have tended to be on the inside edge of the reef, where detrital matter has accumulated under conditions of sea exclusion.

Other characteristics of the structures penetrated have been the high proportion of unconsolidated material, the presence of weathered layers of reef and the inclusion of skeletal material of terrigenous sources. The accretion of coralline debris in the lagoon occurs with very little compaction by waves so that the resultant rock contains many cavities. In fact, beneath large massifs of coral thrown over the reef by the swell and deposited on the lagoon margin, there are caverns due to the inability of sediment falling vertically to fill areas underneath them. These large sections of reef which have been transported across the reef may have been exposed to the atmosphere long enough for weathered qualities to be incorporated in them before burial. This has been assumed to indicate emergence of the reef above sea-level<sup>27</sup>.

The nutrient-rich volcanic soils soon have flora and fauna established on them even though they are subject to excessive erosion. When land-slides occur through denudation, vegetation and animals alike would be thrown into the sea. A small proportion would become lodged in the reef, especially in the sheltered lagoon zone, and so be buried with it in the volcanic mound. Only those elements which have a skeletal constitution that can withstand the decaying process would be available for historical demarcation. Ladd and Tracey<sup>28</sup>, for example, have located a snail shell deep in a reef structure. Such terrigenous material could also float long distances across the ocean to be deposited in the detrital margin of a distant lagoon.

The hole drilled on the swellward margin in the Eniwetok atoll struck the basaltic base 450 ft. below that on the leeward section. This can be explained by the longer time of penetration of this portion of reef and the greater weight and vibration present there. Even if the atoll were to act as an integral structure the tilting of the 'ring' is only of the order of 1 in 240, a very modest grade in differential settlement (Fig. 3b).

Shepard<sup>10</sup>, in summarizing the findings of the two Eniwetok drill holes, records: "The sections were very similar down to 1,400 ft. but strikingly different below. The deeper hole encountered Globigerina-rich limestone, apparently deposited in somewhat deeper waters than those in which the lagoonal sediments of the shoaler hole were laid down". As noted earlier, the deeper hole was on the swellward side of the atoll, which had grown first. Thus, when it was undergoing tilting, prior to the lagoon being enclosed, deep-water oozes could have penetrated the void left on the inside of the reef. These would have become deposited in the limestone, which, nevertheless, was of shallow water origin. The leeward reef would not have suffered such wave action and hence would not have tilted and provided entrance for deep-water organisms. As the reef completed its encirclement, any outward deflexion of the swellward reef would not have been accompanied by the incursion of deep water. Thus the top 1,400 ft. of both bores were similar, indicating that this depth of subsidence had occurred after the lagoon had been more or less completely surrounded.

The sinking of the wedge-shaped reef into the basaltic debris must have some effect on the zone in close proximity to it. Only one of the holes in Eniwetok Atoll penetrated the basement. It was reported<sup>29</sup> that a flow structure was exhibited in the olivine basalt. The alteration of the basalt indicated that it was carried out below the ocean-bottom rather than in hydrothermal conditions. This is satisfied by the subsidence theory submitted since the point of the wedge is considered to be well removed from the surface of the mound, as illustrated in Fig. 5. Compare the limestone slab concept of Fig. 1.

There is an urgent need to drill through a lagoon floor to establish the thickness of the calcareous debris, the

Fig. 5. Suggested section of atoll showing probable strain lines in the foundation material

volcanic debris and the depth to the core of the volcano. Apart from any large massifs of reef which may have been carried into the crater during its inundation, the calcareous matter in any such bore should be insignificant compared with the basaltic content, which should begin just below the marine limestone of the lagoon floor. A hole drilled into the seaward terrace should exhibit reef debris down to about 40 fathoms after which basalt should appear for extended depths. The location of the bore on the periphery will dictate the nature of the basalt, either as *in situ* or accreted material. In any future bores the compaction and flow of the foundation material should be examined thoroughly.

**Seismic information.** Seismic surveys of atolls have been conducted with a view to determining the characteristics of the foundations. These have not been extremely successful because the readings have been interpreted in terms of a thick slab of limestone resting on top of a volcanic mound, above which the reef is supposed to sit. Irregularities in refraction arrival times have indicated differing degrees of consolidation for material beneath the lagoon. This could occur even when fragmented basalt existed throughout the whole mound due to the differing conditions under which it might have been placed. For example, it could be present through volcanic action alone, be deposited by wave action, or be dumped during the crater inundation. The core rock beneath could exhibit yet another velocity. The thicknesses and slopes of the various strata could vary significantly from one volcanic mound to the next, depending on the height and nature of the eruption and wave forces exerted on it. The fragmentary nature of much of this material could well be interpreted from seismic tests as calcareous sediment of similar compaction.

The existence of the atoll as a cylinder or of a conical shell, extending down some hundreds of feet into the volcanic mound, could result in spurious reflexions in any seismic survey. The near horizontal shootings would be influenced more than those of steeper angle. But even results obtained from borsholes in the reef could produce anomalous results, if thought to emerge from an extensive slab of limestone.

### Guyots

Guyots are closely related to atolls and therefore any explanations submitted for the origin of one should readily account for existence of the other. Hess<sup>22</sup> and Hamilton<sup>23</sup> have provided extensive descriptions of guyots. In general they can be considered dome-topped mounds at about 800 fathoms with sides that concave upwards. Corals as well as basalt have been dredged from their tops and across their breaks in slope. It is thought that guyots were originally a group of basaltic islands which became eroded by waves and had coral colonies established on them. Having not developed fully they were purported to have been submerged below the level of subsistence, after which the guyots were carried down to their present level by isostatic adjustment or other sub-crustal forces. Emery, Tracey and Ladd<sup>24</sup> have outlined the differences between atolls and guyots and the following observations are taken from their paper and explained.

Volcanic rocks occur at the rims of guyots but only low on the flanks of atolls. Because of the variable fineness and erodability of volcanic mounds some may never provide stable foundations for coral colonization, especially

in an adverse wave climate. Thus, even before or just after reef formation, the mound may be eroded below subsistence-level. Because of the lack of a protective apron, generally provided by reef debris, the basalt becomes eroded to wave base which, over geological time, could be considered to be about 65 fathoms. Further spreading of this friable material would be accomplished by standing waves produced in the area by reflexion from adjacent atolls. Tidal oscillations in mid-ocean should not be underrated as a means of moving this fine sediment.

Side slopes on the upper reaches of atolls are much steeper than equivalent zones of guyots. As explained previously, the terrace protects the top of the atoll mound but the clapotis, set up around most of the reef periphery, help remove material from the seaward edge. The incidence of standing waves near guyots is not so great and hence the material rests more or less at the angle of repose.

**Profiles.** The guyot has a rounded profile compared with the sharp reef edge of atolls. It is likely that any reef on a guyot is only partly formed, so that it does not project far from the surface of the mound. During the ensuing subsidence it may sink into this foundation. The final distributing agent at the greater depths will therefore smooth the surface from a dome at the centre to a smooth curve at the edge. Atolls, on the other hand, have a non-erodable edge in the form of reef or seaward terrace.

The tops of guyots are smoother than the knoll-filled lagoons of atolls. From previous discussion, it will be recalled that coral growth does not commence until sediment movement is negligible. Hence, until the boundary reef has encircled the lagoon, conditions could not exist for knoll formation. Since a guyot is not likely to have reached this stage of maturity the final touches to the coral complex could not be expected.

The highest point of a guyot is at its centre, whereas that of an atoll is at its edge. The coral reef, which survives on an eroding mound to form an atoll, provides a fixed framework about which denuding or aggrading processes proceed. It also provides debris which is deposited at the boundary of the lagoon. Coral growth and carbonate precipitation add material for the lagoon floor. The resulting accretionary pattern is therefore a saucer-shaped basin.

Considering the possible reasons for the present depths of guyots, the foregoing authors<sup>22</sup> found little satisfaction in eustatism, sinking of the entire sea floor or isostatic adjustment under individual mounds. Age cannot provide the answer either, because similar Foraminifera are found on both atolls and guyots. However, wave-induced slumping appears to account for most of their features. The rapid erosion effected by surface waves on recently erupted volcanic material<sup>25</sup> serves to indicate the consequences that could be expected over thousands of years on basaltic debris when it is not protected by a calcareous sheath.

### Eustatic Implications

The theory of atoll origin outlined here does not invoke change in sea-level at any stage. This complements the approach of many other research workers, as noted in the historical background outlined. However, I may be a little less concerned with this situation than most writers on the subject, since I have yet to be convinced of eustatism by the varied but often anomalous data submitted in its defence. It is hoped to discuss this issue in detail in the near future.

For the present, the explanations submitted for coral development should be judged on their merits, particularly for their rationality and harmony. Observations already recorded should be checked against them in order to prove their validity or otherwise. Perhaps proposed programmes of research could include activities specifically

chosen to test some of the predictions made, as, for example, those in respect of data from future boreholes.

## NEWS and VIEWS

### The Council for Scientific and Industrial Research

THE final report of the Council for Scientific and Industrial Research, for the year 1964, records gross expenditure during the year ended March 31, 1964, of £23,178,017, compared with £19,479,540 for the year ended December 31, 1963 (Pp. iv+70. (Cmd. 2705.) London: H.M.S.O., 1965. 6s. 6d. net. See also p. 671 of this issue of *Nature*). This is reduced to £20,759,733 by various receipts from industry and other sources for services rendered, of which £1,159,141 was from other Government departments and £914,414 from industry, £213,275 being received by the National Physical Laboratory. The net increase on 1963 was £3,528,186, while staff rose from 6,732 to 6,992 during the calendar year. Grants for special researches rose to £3,877,313, compared with £3,297,186 in 1963, contributions to the European Organization for Nuclear Research from £1,700,000 to £1,980,000, and there is a new item of £585,236 for the European Organization for Space Research and Preparatory Commission.

Postgraduate training awards totalled £2,522,920 (£1,735,067 in 1963) and the 1,741 new research studentships brought the total current at the end of the year to 4,142; there were also 735 advanced course studentships and 180 research fellowships, of which 709 and 111, respectively, were new. Of the 4,142 current research studentships, 547 were in biology and biochemistry, 291 in chemical engineering and metallurgy, 1,181 in chemistry, 202 in electrical and 357 in other fields of engineering, 271 in geology, 113 in human sciences, 353 in mathematics, and 827 in physics. The advanced course studentships were distributed mainly in engineering, other than electrical (149), mathematics (184), and physics (107), with 75 in the human sciences, 53 in chemistry, 44 in chemical engineering and metallurgy, 42 in geology, 41 in electrical engineering and 40 in biology and biochemistry. Of the research fellowships, 66 were in chemistry, 42 in physics and 34 in biology and biochemistry.

Grants for special researches totalled 1,335, 617 being new, and of the 1,335, totalling £15.9 million, 302, valued at £2.15 million, were in chemistry, 223 (£2.08 million) in technology, 204 (£1.27 million) in biology, 161 (£1.13 million) in physics, 109 (£1.34 million) in metallurgy and

materials, 107 (£935,844) in geology, and 49 (£3.14 million) in nuclear physics. An earmarked grant of £34,325 over three years was made to the Water Research Association for an investigation of the feasibility of desalting sea and brackish waters for water supply in Britain, and one of £39,685 to three research associations for a joint three-year investigation into industrial dust hazards.

There were increases in the net expenditure on all branches of the Department's work during the year, the major increases being for the National Physical Laboratory (£2,486,304 gross; £2,164,502 in 1963); the Geological Survey and Museum (£754,785; £649,807); radio research (£479,157; £379,041); road research (£1,204,067; £1,086,674); and building research (£948,366; £858,271). For fire research the corresponding figures are £179,539 and £170,605; for forest products research, £228,756 and £216,682; for hydraulics research, £313,125 and £266,868; Laboratory of the Government Chemist, £541,669 and £524,375; National Chemical Laboratory, £451,724 and £431,416; National Engineering Laboratory, £1,086,286 and £1,006,609; Torry Research Station, £279,218 and £252,709; Tropical Products Institute, £234,921 and £230,437, receipts making the former figure a credit of £88,088; Warren Spring Laboratory, £557,172 and £538,554; and Water Pollution Research, £218,768 and £199,932. Expenditure on the National Lending Library for Science and Technology increased from £335,827 to £380,803; on headquarters administration from £678,775 to £750,099; and annual grants to research associations from £2,073,565 to £2,384,446. Special assistance to industry decreased from £81,209 to £63,049.

### Chemical Physics in the University of Manchester :

Prof. G. Allen

DR. G. ALLEN, at present lecturer in chemistry and reader-designate in the University of Manchester, has been appointed to a newly established chair of chemical physics at that university. Dr. Allen was educated at Tupton Hall Grammar School, Claycross, Derbyshire, and the University of Leeds, where he obtained a B.Sc. degree in 1949 with first-class honours in chemistry. In 1952 he was awarded a Ph.D. degree by the University

of Leeds for his work in physical chemistry and in the same year was appointed post-doctoral Fellow at the National Research Laboratories, Ottawa, where he remained until 1954, when he was appointed assistant lecturer in chemistry at the University of Manchester. He was promoted to lecturer in 1956 and reader-designate earlier this year. His research work has been mainly in the field of spectroscopy and polymer science and he has published numerous papers on these and other subjects in learned journals.

#### Psychology In the University of Reading:

Prof. Magdalen D. Vernon

PROF. MAGDALEN D. VERNON, who has been professor of psychology in the University of Reading since 1956 (*Nature*, 178, 777; 1956), having been appointed lecturer in 1946 and later senior lecturer and reader, retires from her chair in 1967.

Dr. M. Treisman

DR. M. TREISMAN has been appointed to succeed Prof. Vernon. He studied medicine in the University of the Witwatersrand during 1947-52. He then practised in South Africa until 1954, when he entered the University of Oxford to read psychology and physiology, holding the Theodore Williams scholarship in physiology. He obtained first-class honours in these subjects in 1956. During 1956-59 he carried out research, and was a Senior Hulme Scholar at Brasenose College, and during 1958-60 he was a Wellcome Associate of the Royal Society of Medicine. He obtained his D.Phil. in 1962. Dr. Treisman was appointed junior lecturer in experimental psychology in the University of Oxford in 1959, and four years later was promoted to his present position of lecturer. Dr. Treisman's research has been mainly in the fields of sensation and perception. He has been interested in the central factors affecting sensory discrimination, and especially in applying statistical decision theory to elucidate how information given in one modality can affect discrimination in another. This has led to work on auditory masking, discrimination during sleep, and other problems. He has also worked on the scaling of subjective magnitudes, the re-interpretation of certain traditional sensory 'laws', and on temporal discrimination.

#### Geography In the University of Cambridge:

Prof. H. C. Darby

PROF. H. C. DARBY, who has been appointed to the chair of geography in the University of Cambridge, has held the chair of geography at University College, London, since 1949. He was previously John Rankin professor of geography at the University of Liverpool (1945 until 1949). Prof. Darby was appointed to a lectureship at Cambridge in 1931 and elected Ehrman Fellow at King's College the following year. During the Second World War, following a short period in the Army, he was attached to the Intelligence Department of the Admiralty. While at Liverpool, he also held a Leverhulme Research Fellowship. Since his appointment to London, he has been a visiting professor to the universities of Harvard, Chicago and Washington State. Prof. Darby has made the field of historical geography very much his own and has greatly stimulated interest in the subject on both sides of the Atlantic. His earlier work was on the medieval Fenland and the draining of the Fens. As editor and contributor, he is in the process of publishing a reconstruction of the Domesday geography of England. Four volumes of this study have already appeared. His contributions to geography were recognized in 1963 by the simultaneous awards of the Victoria Medal by the Royal Geographical Society and the Daly Medal by the American Geographical Society. Prof. Darby has been president of both the Institute of British Geographers and Section E of the British Association for the Advancement of Science.

He has demonstrated a practical as well as an academic interest in the landscape and resources of Britain, serving as a member of the Royal Commission on Historical Monuments and of the National Parks Commission. He is also a member of the recently formed Water Resources Board.

#### Medical Research Council:

Second Secretary

IN view of the rapid expansion of its work and its increasing involvement in public affairs, the Medical Research Council has, with the agreement of the Secretary of State for Education and Science, decided that the Secretary of the Council shall in future be reinforced by a Second Secretary who shall act as his deputy and alternate in all respects. Because of the Council's increasing concern with the development of biology, it is believed that the Second Secretary to the Council should be recruited from the field of men who have had experience of research, and have distinguished themselves, in the biological sciences. Accordingly, Prof. J. A. B. Gray, professor of physiology in University College, London, has been appointed to this post. Sir Charles Harington has agreed to occupy the post of Second Secretary in an acting capacity until Prof. Gray takes up duty some time in 1966.

Prof. J. A. B. Gray

PROF. GRAY was educated at Clare College, Cambridge, and University College Hospital. He qualified M.B., B.Chir. in 1942 and, after service in the Royal Navy, worked in the Department of Physiology at the National Institute for Medical Research. Thereafter he went with Sir Lindor Brown to the Department of Physiology in University College, London. He was awarded an Sc.D. (Camb.) in 1962 for his work on the mechanisms of sensory receptors, and the title of professor in physiology was conferred on him by the University of London in 1959. From 1957 until 1963 he was secretary of the Physiological Society, and since 1960 he has been dean of the Faculty of Science in the University of London.

#### Research Units

THE Medical Research Council has set up a Demyelinating Diseases Research Unit in the University of Newcastle upon Tyne. The Unit will continue and expand investigations of the mechanisms of demyelination with special reference to the possible virological as well as allergic aspects of multiple sclerosis which were previously undertaken by the Research Group with the same title. The Unit remains under the honorary direction of Dr. E. J. Field, senior lecturer in neuropathology in the University of Newcastle upon Tyne, and Prof. H. G. Miller will continue as the Unit's honorary clinical adviser.

Dr. Wallace Fox has been appointed director of the Council's Tuberculosis and Chest Diseases Research Unit, following the retirement of Dr. P. D'Arcy Hart. The title of the Unit has been expanded to take account of its increasing work in the general field of chest diseases, including carcinoma of the bronchus.

Mr. John Bleby has been appointed director of the Council's Laboratory Animals Centre at the Medical Research Council Laboratories, Carshalton, following the resignation of Dr. W. Lane-Petter.

#### Research Groups

UNDER its scheme of Research Groups, the Research Council is able to provide additional support for the development of research programmes in university departments. The financial provision made available in this way enables the university to expand its staff and other resources devoted to the research in question, on the understanding that, after a stated period, it will assume responsibility for the further support of the work. The Council has agreed to provide the following university institutions with support for the establishment of research

groups: *University of Bristol*: Research Group in Neurosecretion in the Department of Pharmacology (Prof. H. Heller) for research on the ultrastructure and function of the hypothalamo-hypophyseal system, and on the distribution and identification of neurosecretory products and their actions and metabolism throughout the vertebrate phylum. *University of Edinburgh*: Research Group on Bacterial Enzyme Variation, in the Department of Molecular Biology (Prof. M. R. Pollock), for research on the enzymatic basis of variation and adaptation in micro-organisms. *St. Mary's Hospital Medical School, London*: Research Group on the Structure and Biological Activities of Antibodies and Protein Antigens in the Department of Immunology (Prof. R. R. Porter), for research on the structure of antibodies and the means by which their structure enables them to combine specifically with antigens.

#### Academician Nikolai Vavilov Prize

THE Soviet Academy of Sciences has instituted an Academician Nikolai Vavilov Prize, to be awarded for outstanding achievements in genetics, selection and plant breeding every three years, on November 26—Vavilov's birthday. Academician Vavilov was responsible for many major discoveries in biology, and for laying the foundation for many new lines of research in botany, plant breeding, genetics and selection. A large plant collection of more than 300,000 varieties was amassed under his direction, representing the flora of the world; this has formed an experimental base for developing new varieties of farm crops in the U.S.S.R. and abroad. Nikolai Vavilov was the first president of the Soviet Agricultural Academy and headed the plant breeding institute. It is good to record that Vavilov has now, posthumously, been restored, by the Russians, to the honourable place which he rightfully deserves in Soviet science—a place which he has always held in the eyes of Western scientists.

#### The University Grants Committee

To fill vacancies on the University Grants Committee, Mr. Anthony Croeland, the Secretary of State for Education and Science, has announced four new appointments. The new members are: J. W. Atwell, managing director of G. and J. Weir, Ltd., Glasgow; Prof. C. E. H. Bawn, Grant Brunner professor of inorganic and physical chemistry, University of Liverpool; Prof. R. C. Cross, Regius professor of logic, University of Aberdeen; Prof. J. Diamond, Beyer professor of mechanical engineering, University of Manchester. Three members of the Committee, whose terms of office had expired, have been re-appointed. They are: Sir Eric Ashby, Master of Clare College, University of Cambridge; Prof. F. W. Rogers Brambell, Lloyd Roberts professor of zoology, University College of North Wales, Bangor; Prof. C. H. Philips, professor of oriental history and director of the School of Oriental and African Studies, University of London.

#### National College of Rubber Technology

At a meeting held at the Department of Education and Science between representatives of the Department and the University Grants Committee, the Inner London Education Authority, Loughborough University-designate, the Northern Polytechnic, the National College of Rubber Technology and the industry, it was agreed that a postgraduate centre of polymer technology, developing the work at present done at the National College of Rubber Technology, should be established in the new University at Loughborough. The University Grants Committee has invited the University-designate at Loughborough to submit detailed plans as soon as possible for the necessary buildings and equipment for 100 students in the first instance. This is on the understanding that the industry will meet the cost of residential accommodation. It is proposed that the National College shall come

to an end when the new centre has been established, but the Department of Education and Science and the Inner London Education Authority will make arrangements for work, up to and including degree level, to continue and to be developed as necessary in London in order to match the needs of the industry.

#### New Steering Committee for Hydraulics Research

THE Minister of Technology has appointed a Steering Committee to be responsible for the general supervision of the research programme and work of the Ministry's Hydraulics Research Station at Wallingford, Berkshire. This Committee has now established three specialist committees on coastal engineering and harbours, on rivers and estuaries, and on hydraulic structures and hydro-electrics, and an Inter-Departmental Liaison Committee will be appointed to maintain and strengthen links with other Government Departments. These changes came about owing to the fact that the previous arrangements, whereby the Council for Scientific and Industrial Research was advised by the Hydraulics Research Board on the work of the Station, automatically came to an end when the Council and the Department of Scientific and Industrial Research were dissolved on March 31, 1965.

The members of the Steering Committee for Hydraulics Research are: Dr. B. K. Blount (chairman); Prof. J. Allen; Dr. E. Lee; T. A. L. Paton; R. C. H. Russell (director of hydraulics research); E. B. Wright (secretary). The Committee's terms of reference are: "To be responsible to the Minister of Technology for the general supervision of the work of the Hydraulics Research Station and for the allocation of effort thereon within the financial resources assigned to the Station and such other limits as the Minister may impose".

The three specialist committees are to advise the Steering Committee on the programme of work of the Station in the fields for which they are responsible. The chairman of each of the committees is: R. C. H. Russell (coastal engineering); Prof. J. Allen (rivers and estuaries); T. A. L. Paton (hydraulic structures and hydro-electrics). The other members of the committees have yet to be nominated.

#### Voluntary Services Overseas

IN a written answer in the House of Commons on July 9, Mr. A. E. Oram, the Parliamentary Secretary to the Ministry of Overseas Development, stated that the number of graduate volunteers serving overseas under the Voluntary Service Overseas Scheme had risen from 36 in 1962-63 to 255 in 1963-64, to 507 in 1964-65, and was expected to reach 900-950 in 1965-66 and 1,300 in 1966-67. On July 13, also in a written answer, Mr. Oram stated that of 113 short-term appointments, mainly for agricultural graduates, which the Ministry of Overseas Development or the Department of Technical Co-operation had been asked to fill in Africa, during mid-1962 to mid-1965, 48 were to research posts and 65 to advisory or executive posts. Of these 113 officers, 36 had had formal training in tropical agricultural subjects as postgraduate students, and most of the others would have acquired specialized knowledge of tropical agriculture before selection. He estimated that the Department would probably make about 60 appointments in the next 12 months, of which about one-third would be for research.

#### University Foundation of Brussels

THE forty-fourth annual report of the University Foundation of Brussels covering the year ended September 30, 1964, in which grants totalling 6.3 million francs were made, includes a tribute to its honorary President, Baron Holvoet, on his ninetieth birthday (Pp. 190. Bruxelles: Fondation Universitaire, 1965). Study grants totalling 561,000 francs were made to 19 students at the universities of Brussels, Louvain, Liège and Ghent, and five subse-

diaries of 60,000 francs for studies abroad in the universities of Paris, London and Cambridge and at the College of France. Subsidaries to scientific works amounted to 743,000 francs, and to scientific periodicals 2.4 million francs, while scientific associations received grants amounting to 903,000 francs and another 30,000 francs went to university associations. Progress is reported with the *Index of Scientific Publications*, of which two volumes are to appear in 1965, and the report includes a first list of periodicals which it is proposed to microfilm, as well as notes on relations with other institutions. Under the heading "Belgian American Educational Foundation" is given a list of bursars nominated in 1964-65.

#### Euratom Information

*Euratom Information*, issued by the Centre for Information and Documentation, Euratom, Brussels, is printed in German, French, Italian, Dutch and English. No. 3, Volume 3, March 1965, lists scientific and technical publications issued in connexion with the Euratom/United States Joint Research and Development Programme, or the Joint Nuclear Research Centre, including reports of the European Atomic Energy Community. Lists of patents and of research contracts are provided, and each section has indexes of authors, inventors, firms and organizations.

#### Scientific Research in British Universities and Colleges

THE latest edition of *Scientific Research in British Universities and Colleges* for the year 1964-65 has been published by H.M.S.O. on behalf of the Department of Education and Science and the British Council (Vol. 1: *Physical Sciences*. Pp. xix+368. 37s. 6d. net. Vol. 2: *Life Sciences*. Pp. xviii+404. 40s. net. London: H.M.S.O., 1965). This invaluable publication outlines scientific research in progress in British universities, colleges of advanced technology, national colleges, regional technical colleges in England and Wales, and equivalent colleges in Scotland and Northern Ireland. So far as possible, all research undertaken within faculties of science, medicine, engineering, technology and agriculture is included, as well as work of a scientific nature occurring within other faculties. This year's publication differs somewhat from previous years' editions. Because of an increasing amount of material, the publication has been arranged in two volumes and the arrangement is now according to subject. Volume 1 contains the physical sciences, both pure and applied, and Volume 2 the life sciences, including medicine and agriculture. Certain inter-disciplinary subjects (biochemistry, etc.) are included in both volumes. Each volume is divided into broad subject fields and within each field the material is arranged by university/college departments. As in previous editions, each entry includes the head of department and the names of permanent staff actually engaged in supervising research. The material for the universities was collected by the British Council and for the colleges by the Department of Education and Science. While the new style of the publication offers many advantages, it would have been a considerable help if the page numbers had been dropped to the base of the page and if the page headings had been brought to the outer margins; this arrangement would have made reference from the indexes considerably easier.

#### Sir William Jackson Hooker

AMONG botanists throughout the world, the name of Sir William Jackson Hooker is remembered for his inspired directorship of the Royal Botanical Gardens at Kew, and for passing on the good work to an equally eminent son when he died on August 12, 1865. Hooker senior was educated at Norwich School, and being of independent means was able to devote a lifetime to science. He travelled extensively in Europe in his

research work, and later travel brought him perpetuation in Mount Hooker in the Rocky Mountains as well as in the order of mooses, Hookeriales. On returning from an expedition to Iceland the ship in which Hooker was travelling caught fire and much of his collected material was lost. However, his memory was so keen that he was still able to publish a review of the work which he had carried out. He set up at Halesworth, Suffolk, a herbarium which rapidly gained international renown. Later he gave the herbarium, together with his fine library, to Kew. Although it was his son, Sir Joseph Dalton Hooker, who graduated M.D. at Glasgow, Hooker senior became linked with that University through his election to the chair of botany in 1820 at the age of thirty-five. In 1841 came his appointment as director of Kew, and it was there that Hooker's genius showed itself to the full. Through him the great collections of algae, lichens, ferns and other plants were greatly enriched. Apart from published works such as his two-volume *Musci Exotici* dealing with foreign mooses, and his editing of the *Flora Londinensis* of William Curtis—works greatly enhanced by Hooker's abilities as artist and illustrator—he found time to edit many journals, including the *Botanical Magazine* and the *London Journal of Botany*. His son kept up the good traditions of the Hooker family both through his expeditions and published work, and is remembered, among other things, for his encouragement of a raw youth named Charles Darwin.

#### Perfumes against Pests

PESTS of the same family as carrot fly feed on the blossom of Umbelliferae and may be controlled by spraying the headlands. This observation suggested the possibility of using scents to attract and trap insects as an alternative to pesticides, and the Henry Doubleday Research Association undertook a pioneer experiment to test the idea (*Perfumes Against Pests*. Pp. 51. Bocking, Braintree, Essex: Henry Doubleday Research Association, 20 Convent Lane, 1965. 3s. 6d.). A range of twelve of the cheaper oils, seven from the order Umbelliferae and the remainder from plants used extensively for flavouring, were diluted with isopropyl alcohol and added to 10 per cent solutions of brown sugar. The solutions were placed in jars covered with a 3/16-in. square hole mesh, to exclude bees and wasps, and the traps were usually sited at a sheltered position a short distance from the crop so as to attract the adult pests before egg laying. For fruit pests, the traps were hung in trees or set between bushes. The catches were analysed and tabulated and some preference trends indicated that coriander oil was best for cabbage root fly, onion fly and celery fly and had a broader spectrum than sweet fennel oil. Promising results were also obtained with parsley seed, dill, cumin seed and caraway oils, and from an apple blossom synthetic scent, and there were suggestions that both Barbados and Demerara sugars were attractants. The Association is prepared to supply outfits for further study.

#### Rutherford Memorial Lecture and Scholarships

UNDER the terms of the scheme to commemorate Lord Rutherford of Nelson, the Council of the Royal Society has made the following appointments. *Rutherford Memorial Lecturer*, Prof. P. I. Dee, professor of natural philosophy in the University of Glasgow, to be Rutherford Memorial Lecturer for 1965 in Canada, and to deliver the Lecture in Saskatoon on September 29, 1965. *Rutherford Scholarships*, Mr. S. D. Bradshaw, of the University of Western Australia, Perth, to a Rutherford Scholarship for three years, to work for the first year at the University of Sheffield (with arrangements for the subsequent years to be made later) on comparative studies on the factors controlling the secretion of adrenal hormones in mammals and reptiles with particular reference to the

role of the pituitary gland and the kidney; Mr. B. J. Frost, of the University of Canterbury, New Zealand, to a Rutherford Scholarship for three years to continue working in the Department of Psychology, Dalhousie University, Halifax, Canada, on an investigation of the interaction of excitatory and inhibitory processes in colour vision.

#### The Paul Instrument Fund Awards

THE Paul Instrument Fund Committee has made grants as follows: £1,000, as a supplementary grant, to Prof. W. R. S. Garton, professor of physics, and Dr. R. C. M. Learner, research associate at the Imperial College of Science and Technology, for completion of the construction of a high-resolution, broad-range spectrograph; £3,200 to R. L. Gregory, university lecturer in experimental psychology and Fellow of Corpus Christi College, Cambridge, for the development and building of an instrument designed to minimize atmospheric and other disturbances in astronomical telescopes; £2,500 to Dr. W. J. Jones, of the University Chemical Laboratory and Fellow of Trinity College, Cambridge, for the construction of laser apparatus for the excitation of Raman spectra; £1,850 as a supplementary grant, to Sir John McMichael, professor of medicine in the University of London and director of the Department of Medicine, Postgraduate Medical School of London, for the continuation of the development of a miniature electromagnetic flowmeter.

The Paul Instrument Fund Committee, composed of representatives of the Royal Society, the Institute of Physics and the Physical Society and the Institution of Electrical Engineers, was set up in 1945 "to receive applications from British subjects who are research workers in Great Britain for grants for the design, construction and maintenance of novel, unusual or much improved types of physical instruments and apparatus for investigations in pure or applied physical science".

#### University News:

##### Keele

THE following appointments have been made: R. T. Beattie (lecturer in the Department of Psychology); Dr. D. B. Cook (post-doctoral Fellow in the Department of Theoretical Physics and Theoretical Chemistry); T. F. Webber (Research Fellow in the Department of Biology).

##### London

DR. A. N. DAVISON has been appointed to the chair of biochemistry tenable at Charing Cross Hospital Medical School. The following readers have also been appointed: Dr. A. P. Mathias (biochemistry, tenable at University College); Dr. J. L. Knill (engineering geology, tenable at the Imperial College of Science and Technology). The following titles have been conferred: *Professor*, Dr. M. Freedman (anthropology, in respect of his post at the London School of Economics and Political Science); Dr. A. L. Greenbaum (biochemistry, in respect of his post at University College). *Reader*, Dr. J. D. Billimoria (chemical pathology, in respect of his post at Westminster Medical School); Dr. A. J. Smith (geology, in respect of his post at University College); Dr. W. M. Watkins (biochemistry, in respect of her post at the Lister Institute of Preventive Medicine).

##### Manchester

THE following lecturers have been appointed: B. Cox and Dr. T. R. Wilson (pharmacology).

##### Newcastle upon Tyne

THE following lecturers have been appointed: Mr. D. Brook (statistics in the Department of Mathematics); Dr. R. H. Paim and Mr. R. Virden (biochemistry); Mr. B. J. Mifflin (plant science).

##### Sheffield

THE following lecturers have been appointed: Dr. G. Coleman (biochemistry); Dr. T. F. Mortimer (pathology); Dr. W. T. Raynes (chemistry). The title of reader in botany has been conferred on Dr. J. Webster.

##### Southampton

THE following appointments have been made: *Reader-ships*, Dr. A. W. Bright (electrical engineering); Dr. L. G. E. Bell (zoology); *Senior Lectureships*, W. A. Matthews (psychology); *Lectureships*, K. J. Binns (electrical engineering); Dr. J. A. Betts and D. R. Wilkins (electronics); Dr. F. A. Bostock, Dr. M. S. P. Eastham, I. J. Ketley, L. G. Proll, Dr. B. S. Westcott, N. L. Biggs, G. M. Phillips and P. J. Taylor (mathematics); Dr. R. D. Wills (physics); Dr. W. T. Drabble, Dr. B. J. Parsons and Dr. G. N. Woodruff (physiology and biochemistry); Dr. F. S. Billett (zoology).

#### Announcements

THE Alvarenga Prize for 1965 has been awarded by the College of Physicians of Philadelphia to Dr. Harry F. Harlow, director of the Primate Research Center, University of Wisconsin, Madison, for his work on social deprivation in monkeys.

At the annual general meeting of the Royal Statistical Society on June 16, Mr. L. H. C. Tippett was elected president for the year 1965-66. Mr. B. P. Emmett, Miss S. V. Cunliffe and Dr. J. A. Heady were re-elected honorary secretaries and Mr. W. Rudoe was elected honorary treasurer. Prof. C. R. Rao was awarded the Guy Medal in Silver of the Society.

A REGIONAL meeting of the Association of Applied Biologists will be held in Newcastle during September 14-17. Further information can be obtained from F. Blackburn, Department of Plant Science, the University, Newcastle upon Tyne 1.

THE 452nd meeting of the Biochemical Society will be held jointly with the Italian Biochemical Society in Santa Margherita during September 7-8. Further information can be obtained from the Biochemical Society, 20 Park Crescent, London, W.1.

AN international colloquium on "The Optical Properties and Electronic Structure of Metals and Alloys" will be held in Paris during September 13-16. Further information can be obtained from Prof. F. Abelès, Institut d'Optique, 3 Boulevard Pasteur, Paris 15.

A GENERAL discussion of the Faraday Society on "Intermolecular Forces" will be held at the University of Bristol during September 14-16. Further information can be obtained from the Assistant Secretary, the Faraday Society, 6 Gray's Inn Square, London, W.C.1.

A MEETING of the British Radio Spectroscopy Group on "Magnetic Resonance in Metals" will be held in the University of Leeds during September 13-14. Further information can be obtained from Dr. E. F. W. Seymour, Department of Physics, the University, Leeds 2.

AN international conference on "The Microwave Behaviour of Ferrimagnetics and Plasmas" will be held at the Institution of Electrical Engineers during September 13-17. Further information can be obtained from the Secretary, Institution of Electrical Engineers, Savoy Place, London, W.C.2.

A CONFERENCE on "Machines for Environmental and Materials Testing", organized by the Institution of Mechanical Engineers and the Society of Environmental Engineers, will be held at the Manchester College of Science and Technology during September 8-10. Further information can be obtained from the Conference Section, Institution of Mechanical Engineers, 1 Birdcage Walk, London, S.W.1.

## RECENT DEVELOPMENTS IN THE OIL INDUSTRY OF RUMANIA

IT is rare indeed these days that an opportunity occurs to obtain first-hand information of contemporary developments, both technical and economic, of a major industry in an 'Iron Curtain' country, more especially when this is presented in English and, perhaps what is even more surprising, by means of an elaborate series of photographs surveying indoor and outdoor activities within that industry. That this has been most successfully achieved in the case of the oil industry in Rumania is attested by a recent publication entitled *Oil—Natural Gas—Petrochemistry in Rumania*\*. The purpose of this publication is adequately summed up in the introduction: "The present album includes a brief survey of the development of the Rumanian oil industry, as well as facts and figures related to its present-day evolution; the photos—representing the images of the main sectors of the oil and petrochemical industry and socio-cultural achievements in this field—illustrate the upsurge taken in recent years by the oil industry as well as its future prospects". The photographs, in black-and-white and in colour, are excellent; they account for considerably more space than the descriptive text, the latter being essentially brief summaries of progress over the years, but with obvious emphasis on what has happened since the advent of the Rumanian People's Republic.

"A Brief History of the Rumanian Oil Industry" is the first heading; this traces events back to 1857 when production of kerosene was in fact the industry as then established, the first kerosene refinery plant being built near Ploiești, while Bucharest, the capital, was the first town in the world to be illuminated with kerosene. The gasoline stage dates from 1898 with production from oil-extraction pits about 250 m deep. With introduction of mechanical methods of drilling, oil production steadily rose, to be seriously interrupted by the First and later the Second World Wars. Nationalization of the industry began in 1948 and this is proclaimed "... the starting point for the impetuous development of the oil industry in Rumania". The second heading, "Well Drilling and Oil and Gas Production", records the fact that, compared with the crude oil production of Rumania for 92 years before 1948, "... in 15 years alone (1949–1963) more than 145 million tons were produced, i.e., some 90 per cent of the overall production before nationalization". Modern geological and geophysical methods greatly contributed to the discovery and exploitation of new and rich oil and natural gas pools in Oltenia, Western Wallachia and Moldova. Apart from oil, methane has proved one of the richest natural resources of the country; its occurrence is widespread and at 99.4 per cent pure methane it is claimed that Rumanian natural gas is unique in this respect throughout the world; output at 10,387 million m<sup>3</sup> of methane in 1963 was at that time a record for the country; since then, to meet industrial and household demands for the gas, the methane transportation pipeline network is being expanded to 4,000 km.

The section on "The Oil-Processing Industry and Petrochemistry" notes that, in recent years, important units for processing crude oil have been commissioned, among which are specifically mentioned the refineries at Dâmbovită and Onești in Moldova, the oil plant at the Teleajen refinery, and the catalytic reforming complex at the Brazi refinery. In the petrochemical field, the oil industry now produces (from methane, etc.) ammonia, high-concentration nitric acid, ammonium nitrate, methanol, formaldehyde, urea and acetylene; from the urea, aminoplasts and adhesives for the wood-processing industry are obtained. The range of methane carbon blacks

has been increased and a polymethacrylic resin 'Stiplax' is now in production. Further petrochemical plants are being built, to include new nitrogen fertilizer plants, plastics production, for example, polyvinyl chloride, polyethylene and polypropylene, polystyrene, phenol-formaldehyde resins, polyurethanes, etc.; manufacture of synthetic yarns and fibres is being developed, as also is Rumania's synthetic rubber output based on oil gas; and the 'Danubiana' factory in Bucharest is geared to a production of 1.1 million car and tractor tyres in 1965.

Under the heading "Research Work and Designing in the Oil Industry" the 'indoor' activities of more than 3,000 research workers and designers are briefly discussed; the relevant centres include: the Research Institute for Oil Drilling and Extraction at Cimpina; a Designing Institute for Oil-wells at Ploiești; a Designing Institute for the Oil-Processing Industry, again at Ploiești; here also is the Petrochemical Research Institute; and there is a Research Institute for the Chemical Utilization of Methane at Medias. Photographs of some of the laboratories concerned, equipment, apparatus, pilot plants, etc., leave little room for doubt as to the modern set-up and efficiency of this more academic aspect of the industry.

"Rumania—an Exporter of Oilfield Equipment and Oil Products" is the title of a section of this album devoted to commercial interests of the industry in its trade with other countries. We learn that Rumania now has commercial relations with more than 40 countries as regards its oil products and that new export markets are being opened up in Europe, Asia, Africa and Latin America. Rumania has built a 750,000-ton oil/year refinery at Gauhati, Assam State, India; it claims that "Rumania is now able to design and deliver the necessary equipment and plants for modern refineries of any capacity, working on any raw material and turning out any required product"; her co-operation with the oil industry in Afghanistan, Bulgaria, Burma, Ghana, Indonesia and the United Arab Republic is also noted.

No communication from a Communist country would be complete without some reference to cultural facilities and this publication ends with a section, fully illustrated, dealing with "Living Conditions of Oilworkers". The information given here is impressive, particularly as regards housing accommodation and conditions, social amenities, education, medical care, and recreation. In these respects the industry is true to the modern conception of care of all people concerned in its development and progress, as is such a traditional feature now of the major oil companies operating all over the world. It would indeed be interesting, if not instructive, if only half the information contained in this book were available in the same form from other oil-producing countries behind the 'Iron Curtain'; the aid that such reading (and in this case seeing as well) imparts to better understanding of these countries is both ethically and technically invaluable.

Not content, however, with this challenging essay into world publicity, 1965 sees the first issue of a new official bulletin entitled *Chemistry, Oil and Gas in Rumania*†. Here again the purpose is abundantly clear: to keep the Rumanian oil industry in the forefront of technical and commercial developments and to spread its potentialities world wide. This bulletin is also printed in English; whether in other languages is not disclosed. A synopsis of the contents of Vol. 1, No. 1, is indicative of its scope, which does in fact spread the net wider than just the oil industry. "... the interested circles will find surveys

\* *Oil—Natural Gas—Petrochemistry in Rumania*. Edited by A. S. Bandu, Ana Georgescu, M. Portarescu and S. Sigartan. Pp. 146. (Bucharest: Meridiane Publishing House, 1965.)

† *Chemistry, Oil and Gas in Rumania: News and Commentaries*, No. 1, 1965. Pp. 48. (Bucharest: Centrul de Documentare al Industriei Petrolului si Chimiei, 1965.)

of the articles published in the speciality journals, news related to the research and designing activity, brief plant information, trade notes and statements of visitors of our oil and chemical sector as well as other materials illustrating the steady progress witnessed by the Rumanian oil and chemical industries'. It is significantly added that this Centre will supply, on demand, "articles, summaries and other additional information translated into one of

the international languages, accompanied by photos". This bulletin is in mimeograph type with no illustrations save coloured advertisements on the inside covers; but the contents—research and design, short news, commercial information, patents—books and reviews, etc., if this pattern is followed in future issues are bound to attract attention and to command a keenly interested following of international oil technologists. H. B. MILLNER

## ATOMIC ENERGY IN AUSTRALIA

THE twelfth annual report of the Australian Atomic Energy Commission\*, for the year ending June 30, 1964, deals with the production of uranium in Australia, research activities at the Lucas Heights Research Establishment and in Australian universities, and generally with international relationships and nuclear power developments in various countries.

The financial statement records that capital expenditure was reduced by some £A175,000, but that research expenditure increased by about £A270,000 to nearly £A3 million, largely because of the introduction of improved salary scales for the staff and the increased cost of recruitment of staff. The net operating and capital expenditure for the year was £A3,473,862, an increase of £A287,000 over the previous year. The advance to the Rum Jungle Project was reduced, however, from £A1.58 million to £A720,000.

Uranium continued to be in over-supply throughout the world, but the major cut-backs in production required to stabilize the industry in the Western World are now completed. It is expected that since output will continue to fall as individual mines close down, no additional drastic changes will be necessary, and that in the early 1970's world requirements for nuclear fuel will increase again quite rapidly. During 1963 about 1,200 short tons of uranium oxide were produced and sales during this period were valued at approximately £A5.5 million. Only one sales contract remained in operation in June 1964, and although the United Uranium N.L. expected to complete production during 1964, the final deliveries under the £A5 million contract with the United Kingdom Atomic Energy Authority will extend into 1965. Treatment of stockpiled uranium ore at Rum Jungle is expected to continue at the present level for several years.

The Commission's main research programme is devoted to the investigation of the technical and economic feasibility of a high-temperature, carbon dioxide-cooled, beryllium oxide-moderated, power reactor of the pebble-bed type. The fuel elements consist of a dispersion of thorium oxide and commercial plutonium oxide in beryllia, and the core of the reactor comprises a large number of spheres or pebbles, about 1 in. in diameter, of the fuel material. Four different engineering designs of the reactor system are being studied and these are shown diagrammatically in the annual report. Although considerable effort has been devoted to the various engineering and theoretical physics problems involved, including the development of computer codes for core nuclear studies, the Commission specifically states in the report that there is no commitment to construct a power reactor in Australia.

At the Lucas Heights Research Establishment the high neutron flux materials testing reactor, *Hifor*, continued operation at a power output of 11-MW (thermal) on a 28-day cycle for the whole year, except for a two-month major overhaul period. The small low-power reactor, *Moata*, was used mainly for experiments associated with the performance of systems moderated with beryllium oxide. Alterations were made in the control rod read-out

system, and to the internal graphite reflector. New facilities completed or installed at the Establishment included a large single cell capable of remote-handling of up to 600,000 c. of cobalt-60, and a 3-MeV positive ion Van de Graaff accelerator for fast neutron physics experiments.

The Establishment maintained a good safety record during the year. No serious accident, either radiological or industrial, occurred. A wide range of radioisotopes was produced for use in medicine, research, agriculture and industry, and in addition to supplying Australian requirements, radioisotopes were exported to Japan, India, New Zealand, South Africa and the Philippines. The development of sources of gamma-excited monoenergetic X-rays and their application in industry were given particular attention. Special projects included the production of sources of caesium-134 and thulium-170 for radiographic purposes, and the investigation of the effects of neutron- and gamma-radiation on non-metallic bonding materials such as epoxy resin. Large sources of high specific activity of cobalt-60 can be produced in *Hifor*, and during the year the Commission supplied the Royal Adelaide Hospital with a 1,300-c. source, the Royal North Shore Hospital in Sydney with a 2,160-c. source, and under the Colombo Plan, the Cancer Institute of Madras, India, with a 3,025-c. source. The only significant change during the year in the demand for specific radioisotopes was an increased request for radiography sources in smaller sizes and cylindrical sources of iridium-192 of 1-mm length and 1-mm diameter with an activity of up to 8 c., and similar sources of cobalt-60 with an activity of 1.5 c. were produced to meet this requirement.

The first international conference on "Beryllium-oxide", attended by scientists from six countries, was held in Newport, New South Wales, during October 21–25, 1963. The conference was sponsored and organized by the Commission, and 56 papers were presented for discussion, including 27 from the Australian Atomic Energy Commission Research Establishment. The topics discussed covered aspects of fabrication, structure, physical and mechanical properties, radiation damage and gas-solid interactions. The last day of the conference was devoted to a symposium on the utilization of beryllium oxide in reactors. The proceedings of the conference have been published in a special issue of the *Journal of Nuclear Materials* (1964). In addition to a wide range of booklets, leaflets and other publications on atomic energy, the Commission also published a quarterly journal, *Atomic Energy in Australia*, a quarterly *Radioisotope Newsletter*, and a special 55-page booklet entitled *An Introduction to Nuclear Science* for use in schools. The Commission's film "Atoms for Everyday" was shown on the national television network and a major exhibition, "Australia and the Atom", featuring many aspects of atomic research, production and mining of uranium, nuclear power and the use of radioisotopes, was presented in Brisbane and Newcastle. The Research Establishment held open days during September 26–28, 1963, and some 6,000 persons visited and inspected it.

Research contracts totalling more than £A51,000 were placed with Australian universities. Details of these are

\* Australia. Twelfth Annual Report of the Australian Atomic Energy Commission for the year ended 30th June, 1964. Pp. 80. (Geogee, N.S.W.: Australian Atomic Energy Commission, 1964.)

listed in an appendix to the report. The Commission, together with the ten Australian universities, constitutes the corporate membership of the Australian Institute of Nuclear Science and Engineering, which is governed by the Institute Council consisting of one representative from each of the universities and four from the Commission. All member universities are engaged in training nuclear scientists and engineers and in related research. 112 projects were supported by research and training grants of the Institute, and the expenditure amounted to about £A100,000. Plasma physics, in particular, received special support. An informal conference on plasma physics was held during November 1963, and the research effort at three universities was assisted by providing on loan a special high-speed camera capable of photographing the formation and decay of plasmas. Two other informal

specialists conferences were held at Lucas Heights under the auspices of the Institute—a "Heat Transfer and Fluid Flow" conference during August 1963, and a "Radiation Chemistry" conference during October 1963.

In conjunction with the University of New South Wales, the Commission is to establish an Australian School of Nuclear Technology with headquarters at the Lucas Heights Research Establishment. The facilities of both the Research Establishment and the University will be available to the School. The aim is to promote formal training and education in nuclear technology; and full-time courses of varying length in the science and technology of nuclear reactors, the production and application of radioisotopes, radiological safety and health physics, etc., will be open to students from Australia and overseas.

S. WAINTROUB

## BRITISH CHEMICAL REFERENCE SUBSTANCES

IN late 1963, the General Medical Council and the Pharmaceutical Society of Great Britain agreed to set up a joint authority to prepare and distribute chemical reference substances needed to carry out certain tests and assays described in the *British Pharmacopoeia*, the *British Pharmaceutical Codex* and the *British Veterinary Codex*. The Joint Committee held its first meeting in March 1964, and established a number of panels. Each panel was charged with the task of establishing one or more of these reference substances, and, since these substances might be of value for other purposes, the panels were asked, should it prove impracticable to obtain absolute purity, to ascertain so far as possible the amounts of all impurities.

The first two "British Chemical Reference Substances" have now been made available: digoxin and 2-*t*-butyl-4-methoxyphenol (the most active isomer present in butylated hydroxyanisole); these are required for the *Addendum* 1964 to the *British Pharmacopoeia* 1963, which became official as from June 1, 1965. The reports to the Joint Committee of the panel responsible on the preparation and purity of these substances have now been published.

The digoxin reference substance is required in the assay of digoxin and of its two preparations, the injection and the tablets, and for purposes of comparison (in place of the previously used authentic specimen) in the infra-red identification test. From its examination of the reference substance, the panel concluded that the substance is at least 99.7 per cent pure, containing not more than a total of 0.3 per cent of gitoxin, acetyldigoxin, digoxigenin and digitoxin.

The 2-*t*-butyl-4-methoxyphenol reference substance is required for the assay of butylated hydroxyanisole and in the infra-red identification test. In this case, a purity

of at least 99.85 per cent has been achieved, the balance being made up of very small amounts of 3,3'-di-(*t*-butyl)-2,2'-dihydroxy-5,5'-dimethoxybiphenyl (*bis*-BHA), 2,6-di-(*t*-butyl)-4-methoxyphenol, 4-methoxyphenol and a trace of an unidentified impurity. As well as its pharmaceutical uses, butylated hydroxyanisole has extensive usage in the food industry as an anti-oxidant in oils and fats, and the establishment of this reference substance will be welcomed in fields outside of pharmacy.

Samples of these reference substances are distributed by the Pharmaceutical Society and are available on application to the Assistant Director, Department of Pharmaceutical Sciences, 17 Bloomsbury Square, London, W.C.1, at a cost of £4 10s. for 0.3 g of the digoxin, and £3 for 0.2 g of the 2-*t*-butyl-4-methoxyphenol. Copies of the panel's reports can be obtained from either of the joint secretaries, Mr. T. O. Denston, 44 Hallam Street, London, W.1, and Dr. K. R. Capper, 17 Bloomsbury Square, London, W.C.1.

Because there may be some confusion between "British Chemical Reference Substances" and "Authentic Specimens", both of which are distributed by the Pharmaceutical Society, it is appropriate to explain that the reference substances are samples which have been purified so far as is practically and economically feasible, any remaining impurities having been identified and a limit set on their presence. They are used in assay procedures and to serve as the reference material in tests used to limit the presence of certain impurities in pharmacopoeial and *Codex* substances. Authentic specimens, on the other hand, are only tested samples of good quality commercial material which are needed for certain tests, notably infra-red identification tests, for which a comparison material having the purity of a reference substance is not essential.

## PESTICIDES IN THE ENVIRONMENT

AN advanced study institute on "Pesticides in the Environment and their Effects on Wildlife", sponsored by the North Atlantic Treaty Organization, was held at Monks Wood Experimental Station during July 1-14.

The main purpose of the Institute was to enable those working on the effects of pesticides on wildlife to exchange ideas and to discuss future research. Thirty-four papers were read, and dealt with the background of the wildlife problem and with field and laboratory studies of the effects of pesticides in terrestrial, freshwater and marine environments. Seventy-one scientists from Government

and university laboratories attended the meeting, including chemists, toxicologists and zoologists of eleven nationalities.

The papers and discussions showed that pesticide residues have been detected in a wide spectrum of physical and biological samples from diverse environments, indicating that contamination is widespread. In some instances, harmful effects on wildlife populations were clearly demonstrated, but more frequently the effects of residues are unknown.

It was concluded that in order to understand the effects of pesticides more fully, there was need for more work,

including: routine collection of data; experimental research; use of present knowledge; and dissemination of information. Details are as follows:

**Routine collection of data.** Carefully designed surveys are needed to obtain valid estimates of animal populations to assess effects of changing environmental conditions. Furthermore, it is necessary to measure the accumulation of chemical residues in many physical and biological components of the environment to assess the present and future levels of contamination. Existing studies of residues in Belgium, Canada, Eire, France, the Netherlands, Sweden, the United Kingdom and the United States provide the basis for further research of this kind. Special emphasis should be placed on persistent compounds, and on aquatic species which seem to be especially valuable as indicator organisms. Multiple-detection methods with associated techniques for confirmation of identity should be used wherever possible. Detailed information concerning the total quantity of pesticide used in different countries must be obtained to understand residue data properly, and to predict future trends.

**Experimental research.** There is a need for developing and standardizing analytical procedures, censusing methods and other techniques. Investigators should pay full attention to the use of critical and confirmatory techniques which have already been worked out, and to the statistical treatment of accumulated data. More

work is required on pesticides other than organochlorine compounds. In particular, improved methods of chemical analysis for organophosphorus pesticides and their metabolites should be investigated. The dynamics of pesticides in different environments need to be investigated more thoroughly, including decomposition, physical and biological dispersal and accumulation. Additional investigations are required to resolve the difficulties in using results obtained from laboratory studies to assess possible effects on populations in the field. Long-term field studies are particularly necessary for assessing the effects of persistent chemical compounds and their metabolites.

**Use of present knowledge.** It is necessary to ensure that the great body of existing data be applied, starting at the stage of introduction of a new pesticide, and in considering the introduction of extensive control programmes. Special consideration should also be given to rare species and those of restricted range and special vulnerability.

**Dissemination of information.** To implement the development of research outlined above, it was hoped that members of the Conference would continue to exchange information, and that international meetings of a similar kind to this Advanced Study Institute would be held at regular intervals. An annual list of current research projects would be particularly valuable.

## NOCTILUCENT CLOUDS OVER NORTH AMERICA

By BENSON FOGLE

Geophysical Institute, University of Alaska College, Alaska

IN 1962, when the work reported here began, only one recorded sighting of noctilucent clouds from North America was known. This was the observation reported by Vestine in 1934 (ref. 1). The scarcity of sightings from North America led to the belief that noctilucent clouds did not occur here as frequently as over Europe and the U.S.S.R., where hundreds of such observations have been made during the past eighty years.

A careful literature search made in 1962 uncovered eleven additional records of North American sightings of noctilucent clouds, and an observation programme conducted at College, Alaska, during the summer of 1962 resulted in five more sightings. On the basis of these findings it was concluded<sup>2</sup> that noctilucent clouds occurred over North America more frequently than previously supposed, and that the scarcity of recorded observations was probably due to the lack of informed and interested observers.

To investigate the apparent frequency of occurrence, spatial extent and lifetime of noctilucent clouds over North America, an extensive network of noctilucent cloud observing stations was established in 1963 over Alaska and Canada which in 1964 was extended to Greenland and Iceland. Co-operation in the set-up of this network of stations was given by the Canadian Department of Transport, the Icelandic Meteorological Service, the U.S. Weather Bureau, the U.S. Federal Aviation Agency and the U.S. Air Force Weather Squadrons. Fig. 1 shows the locations of the stations participating in this programme. A *Noctilucent Cloud Observation Manual*<sup>3</sup> was prepared and issued to all participating stations to acquaint the observers with noctilucent clouds. During the summer of 1963, only 33 Alaskan stations and 15 stations in western Canada took part in the programme. This past summer (1964) all the stations shown in Fig. 1 took part, as well as the crews of the Pan American World Airways and Alaska Airlines aircraft flying the Fairbanks-Seattle route.

During 1963, with 48 stations participating, 25 displays of noctilucent clouds were sighted over North America.

During 1964, with 88 stations participating, 57 displays were sighted. These numbers represent reliable sightings. A number of additional reports had to be discarded because of insufficient evidence of a definite display. A complete listing of the nights of the 99 displays of noctilucent clouds reported over North America to date is given in Table 1. It also gives the number and latitude and longitude range of the stations which reported noctilucent clouds on these nights. The low-latitude, artificially produced noctilucent clouds reported by Meinel<sup>4</sup> are not included in Table 1. The date of the display, given by a single number, refers to the night beginning on that date and ending on the following one. The observations listed in Table 1 are presented in Fig. 2 in the form of a histogram and a smoothed curve. The

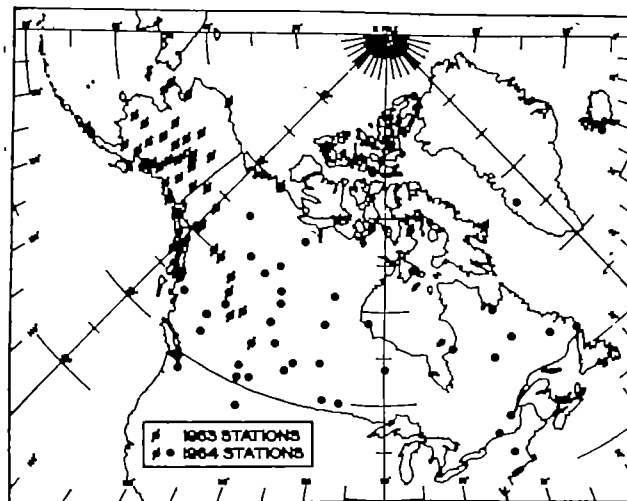

Fig. 1. Network of noctilucent cloud-observing stations over North America, Greenland and Iceland

Fig. 2. Apparent frequency of occurrence of noctilucent clouds over North America based on all the 99 sightings made so far. The histogram represents the number of noctilucent cloud sightings per 10-day interval. The smoothed curve is based on the relation  $N = (a + 2b + c)/4$ , where  $b$  is the frequency in the interval in question and  $a$  and  $c$  are for the adjacent intervals.

histogram represents the number of sightings per ten-day interval. The smoothed curve was derived from the histogram using the smoothing relation  $N = (a + 2b + c)/4$ , where  $b$  is the frequency for the period in question and  $a$  and  $c$  are the frequencies for adjoining periods. This smoothing relation serves to correct at least partially for cloudy nights and other factors, and should represent the actual relative frequencies with greater accuracy than the histogram. The observations given in Table 1 are also

divided according to the number of sightings for different latitude ranges in intervals of 5 degrees. These frequencies are given in Fig. 3 in the form of a histogram and a smoothed curve.

The salient features of the North American observational data of noctilucent clouds are: (1) noctilucent clouds have been observed from late April through late September; (2) the peak of activity is around the end of July; (3) noctilucent clouds occur far more often after the summer solstice than before (27 before and 72 after); (4) the lowest and highest latitude sightings are 45.5 and 76.3 degrees, respectively; (5) the optimum latitude range for observing noctilucent clouds is 50–65 degrees; (6) noctilucent clouds occur as frequently over North America as over Europe and Russia.

Since the observation of noctilucent clouds is restricted to twilight periods when the Sun is between 6° and 16° below the observer's horizon, it is not possible at present to determine the true lifetime of these clouds. Sometimes extensive displays of noctilucent clouds recur for two or more successive nights, but whether they are parts of a distribution that is continuous throughout the intervening day-times is uncertain. Lifetimes of 5–6 h have been measured for two widespread displays—August 11 and August 12, 1963—observed over Alaska and Canada. Particular parts of noctilucent clouds may last for only a few tens of minutes. For example, one well-defined portion of the August 11, 1963, display formed and decayed in a clear portion of the sky in a period of about 30 min.

Sometimes the whole boundary of a noctilucent cloud display can be seen and its area estimated; this may be only a few tens of thousands of km<sup>2</sup>. The extent of sky at the level of 82 km visible from one station is a circular area about 1,000 km in radius; but only a part of this

can be illuminated by sunlight against a dark sky. Twenty-six of the displays observed over Alaska and Canada were too extensive to be all visible from any one station. Combination of the data from many observers indicate that the areas covered by eight of these displays (August 11, 1963; August 12, 1963; June 29, 1964; July 5, 1964; July 11, 1964; July 16, 1964; July 24, 1964; and August 2, 1964) were more than 2 million km<sup>2</sup>. It is possible that noctilucent clouds might at times cover all longitudes around the pole and have an area of order 10<sup>8</sup> km<sup>2</sup>; but this, if true, would be difficult to establish from observations of the kind presently available because they are restricted to twilight, and only stations in a sector of about 90° in longitude can see them at the same time.

A prominent feature of many noctilucent cloud displays is the presence of well-defined parallel bands. These have been identified with systems of waves of various wave-lengths. Only a few wave-lengths have been measured in the past; they range between 7 and 100 km (refs. 5, 6). We have recently developed a simple method for measuring the wave-lengths from individual photographs of noctilucent clouds. The method is based on the constancy of the height of noctilucent clouds at 82 km, and requires good photographs which contain several points the elevation and azimuth angles of which are known. From the photographs, the elevation angle to the pair of bands in question is measured as well as the incremental angle between them. A knowledge of these two quantities is sufficient for determining the wave length. Photographs of three displays of noctilucent clouds observed over North America have been analysed by this method so far. A total of 248 wave-lengths were determined from these photographs and the frequency distribution obtained is shown in Fig. 4. As seen from this curve, the wave-lengths range from about 5 to 100 km, the most frequent value being about 10 km.

Two mechanisms have been suggested to account for the wave structure in noctilucent clouds: internal gravity waves<sup>7</sup> and interface waves<sup>8</sup>. A comprehensive discussion of these mechanisms by Haurwitz<sup>9</sup> indicates it is likely that the short wave-lengths of about 10 km are due to interface waves, and that the longer wave-lengths are due to internal gravity waves. More data on the temperature distribution, wind shear at the mesopause, as well as simultaneous velocity and wave-length measurements are needed to determine with more certainty the cause of the waves.

An examination by Vestine<sup>1</sup> of the noctilucent cloud data for the years 1885–1933 showed that there was no

Fig. 3. Apparent frequency of occurrence of noctilucent clouds over North America as a function of latitude range. The histogram represents the number of noctilucent cloud sightings per 10-day interval. The smoothed curve is based on the relation  $N = (a + 2b + c)/4$ , where  $b$  is the frequency in the interval in question and  $a$  and  $c$  are for the adjacent intervals.

Fig. 4. Frequency distribution of wave-lengths in three noctilucent cloud displays (248 measurements).

Fig. 5. Fluctuation of the apparent noctilucent cloud activity compared to the sunspot cycle for the period 1885–1964. —, Noctilucent clouds/yr.; ---, sunspot No./yr.

apparent correlation of noctilucent cloud activity with either volcanic activity or meteor showers, but there was some evidence of a correlation with years of sunspot minima. Vestine pointed out that this apparent correlation might be fortuitous since the number of noctilucent cloud observers and interest in these clouds have varied widely over the years. Quiroz<sup>10</sup> re-examined the possible correlation of noctilucent cloud activity with sunspot cycle using a partially complete list of 711 sightings for the period 1885–1963 and found no correlation. We have recently compiled a complete list of the 1,034 noctilucent cloud sightings reported during the period 1885–1964 and compared the frequency of occurrence of noctilucent clouds with the sunspot cycle data for the same period. These results, given in Fig. 5, show that there is no correlation of noctilucent cloud activity with sunspot cycle. A physical relationship between the two, however, is not improbable, since solar-induced variations in the density and temperature of the atmosphere near 80 km could well have an important effect on incoming dust particles and their subsequent redistribution.

# PHASE MODULATION OF GEOMAGNETIC MICROPULSATIONS

By T. J. HERRON

Lamont Geological Observatory, Columbia University, Palisades, New York

THE Geomagnetism Group of Lamont Geological Observatory has recorded variations in the total intensity of the magnetic field with a rubidium vapour magnetometer. High-resolution power spectral analyses of large amplitude, narrow-band *Pc2* micropulsations have been performed by digital computer. A relationship was found in the frequency domain between the *Pc2* activity and longer period *Pc5* micropulsations which indicates that the shorter period signals were phase modulated by the longer period variations.

the natural spectrum, Fig. 2 presents the pre-whitened spectrum with the six dB slope removed. Power density is in units of gammas<sup>2</sup>/c/s. In Fig. 2 there is a series of peaks, somewhat equally spaced in frequency, between 0.015 and 0.04 c/s, which are incorrectly spaced to be due to side lobes of the hamming spectral window.

The high-amplitude, narrow-band *Pc2* micropulsations began on this day at 1,000 h local time and continued until 1,400 h. Fig. 3 shows 1-h spectra of the first and last hours of the 4-h period. Frequency-time analysis of the

Fig. 1. Rubidium magnetometer recording of *Pc2* micropulsations superimposed on long period *Pc5* variations. Lebanon State Forest, New Jersey, 1156–1240 local time, Oct. 25, 1963

The magnetic variations were recorded at a station in the Lebanon State Forest on the New Jersey coastal plain. Part of the data were recorded in digital form on punched paper tape at a sampling rate of once per second. In other cases, analogue records were taken to the laboratory and digitized on an electromechanical instrument. In addition, part of the data were also recorded simultaneously at stations separated several hundred kilometres from Lebanon.

Power spectral analyses were performed on sections of records showing continuous, high-amplitude micropulsations. The typical geomagnetic power spectrum has an approximately six dB per octave rise in power towards long periods<sup>1</sup>. In this investigation, the data were pre-whitened before the spectral analysis was performed by use of a filter which attenuated at six dB per octave towards the long periods and also cut sharply the periods less than the folding period, thus reducing aliasing errors. Smoothing of the raw spectrum was done with a hamming window.

Fig. 1 is a photograph of the rubidium magnetometer record during part of the interval the spectrum of which is shown in Fig. 2. The photograph shows 30 sec period micropulsations superimposed on longer period variations. Fig. 2 shows the spectrum of a 2-h and 13-min section of record, during 11.37–13.50 local time, during an interval when the *Kp* index was at the relatively low values of 1+ and 2+. The spectrum was computed using 3,504 data points at 2.28-sec spacing. Three hundred and fifty lags were used. The frequency resolution was 0.00063 c/s. Since some of the spectral peaks are very marginal and were obscured by the steeply rising curve of

entire interval confirmed what is suggested by Fig. 3, namely, that the average period of the signals drifted gradually, by about 4 sec, towards longer periods during the interval. It was found that a spectrum of about a 2-h interval provided the frequency resolution necessary to show the equally spaced peaks of Fig. 2, but was not so long that the peaks were averaged out by the slow drift in period.

Fig. 4 presents pre-whitened spectra of micropulsations recorded simultaneously at Lebanon and Breezewood, Pennsylvania, 1,000–1,200 h local time, on a disturbed day when the *Kp* index was 4-. These stations are separated by 318 kilometres in an east-west direction. The spectra were computed using 2,400 data points at a 3.0-sec spacing. Two hundred and forty lags were used. The frequency resolution was 0.0007 c/s. At both stations the analogue records showed short period *Pc2* micro-

Fig. 2. Power spectrum c/s a 2-h and 13-min interval, including section of record in Fig. 1

pulsations superimposed on longer period variations. The close correspondence of peaks between stations is evident. Again the pattern of nearly equally spaced peaks is seen.

A phase modulated signal has a frequency spectrum with a peak at the carrier frequency plus an infinite number of sidebands separated from the carrier by integral multiples of the modulating frequency<sup>1</sup>. The phase modulated signal can be represented as:

$$a = A \sin(2\pi Ft + (\varphi_0 + \Delta\varphi \cos 2\pi\mu t))$$

where  $F$  is the carrier frequency,  $\mu$  the modulating frequency,  $\varphi_0$  the phase angle, and  $\Delta\varphi \cos 2\pi\mu t$  the phase deviation in radians. The sidebands of a phase modulation frequency spectrum diminish rapidly in magnitude when they are displaced from the carrier frequency by more than  $\mu\Delta\varphi$ , or equivalently, when the number of sidebands exceeds  $\Delta\varphi$ .

If the highest peak in Fig. 2 is assumed to be the carrier frequency, then  $F = 0.0315$  c/s. There are seven peaks on the low-frequency side of the carrier, extending to 0.0150 c/s and spaced an average of 0.00225 c/s apart. If 0.00225 c/s is taken as the modulating frequency  $\mu$ , then  $\mu\Delta\varphi$ , which must be the approximate half-width of the spectrum and which in this case is 0.0165, requires  $\Delta\varphi = 7.3$ .  $\Delta\varphi$  should not be much greater than the number of sidebands, which is so.

The most obvious spectral peak in Fig. 2 is the large one at 0.00250 c/s (400 sec period), which is very close to the assumed modulating frequency. It is suggested, then, that this peak represents the energy of a long-period magnetic variation which phase-modulated the shorter period signals.

In the Lebanon-Breezewood spectra of Fig. 4, the long-period peak has an average value on the two spectra of 0.0032 c/s (312 sec period), a higher modulating frequency than in Fig. 2. Though the spacing of the fine peaks is not entirely regular in Fig. 4, the average spacing

Fig. 3. 1-h power spectra of first and last hours of 4-h interval, 1,000-1,400 L.M.T., Oct. 25, 1963

Fig. 4. Simultaneous power spectra at stations separated 818 km

Fig. 5. Cycle-number versus time plot of wave-train shown in insert

between points A and B is 0.0031 c/s, a wider spacing corresponding to the higher modulating frequency.

A phase deviation of the size calculated (7.3 radians) should be easily visible on a cycle-number versus time plot of a continuous section of a micropulsation wave-train long enough to undergo a full cycle of modulation. Fig. 5 shows such a plot for a 320-sec long amplitude group which occurred during the 4-h interval already referred to. As was seen less well for several other sections of wave-train, the points lay about a straight line in a sinusoidal manner. The maximum phase deviation here is only about 1.5 radians, however. Fourier analysis of micropulsation groups, such as shown in Fig. 5, which occurred during intervals when the long period activity was present, also showed a frequency spectrum consisting of a carrier frequency accompanied by sidebands.

The equally spaced peaks are a very marginal feature on both the power spectra and the Fourier spectra. They can be detected only if very strong micropulsations occur superimposed on large amplitude, long period variations. No clear occurrence relationship was found between the two bands of activity. Twelve high-resolution spectra were computed. In six spectra, where strong Pc2 micropulsations were present, the long-period spectral peaks, which ranged from 312 to 400 sec period, were present and of high amplitude. Of these six, only the spectra shown in this report revealed the phase modulation effect clearly. In the other six spectra, instances were found where either one or the other of the period bands was present alone.

## ORIGIN OF CHONDRITES

By PROF. A. E. RINGWOOD

Department of Geophysics and Geochemistry, Australian National University, Canberra

APPROXIMATELY 90 per cent of the meteorites that fall on the Earth are classed as chondrites. Chemical analyses of chondrites reveal some striking similarities and dissimilarities. The abundances of the major components are remarkably similar when considered in relation to the compositional variations of a comparable terrestrial petrologic class such as basalts<sup>1</sup>. This similarity is so characteristic that in the few cases where chondritic structures are lacking (for example, Type I carbonaceous chondrites) the chemical composition clearly serves to establish genetic affinity with the chondrite class. Superimposed on the general similarities in abundances of major components, there are some systematic differences of comparatively small magnitude which are characteristic of the different major classes of chondrites. One of the principal variations of this type is in the oxygen content. This exercises a major control over the mineralogy of chondrites, which is the basis of their classification<sup>1</sup>. Another is in the total iron content, which is also used for classification<sup>1</sup> (Fig. 1).

Contrasting with the relative uniformity of major element abundances, very large differences exist in the abundances of certain minor elements. For example, chlorine, iodine, tellurium, zinc, cadmium, germanium, lead, bismuth, thallium and mercury are depleted in ordinary chondrites compared with Type I carbonaceous chondrites by factors varying between 5 and 1,000 (ref. 3). Significant but smaller relative depletions exist for many other elements. Apart from mercury, the foregoing elements are only slightly depleted in enstatite chondrites compared with Type I carbonaceous chondrites. However, enstatite chondrites have suffered significant relative depletions (30–80 per cent) in a number of oxyphile elements, for example, calcium, barium, yttrium, rare earths, scandium, chromium, titanium, uranium, thorium<sup>2,4</sup>. The outstanding feature of the trace element abundance patterns is that many elements in all groups of chondrites are depleted compared with Type I carbonaceous chondrites. It would be possible to obtain the compositions of enstatite chondrites, ordinary chondrites and Types II and III carbonaceous chondrites solely by the removal of the appropriate amounts of trace and minor elements from Type I carbonaceous chondrites<sup>1–7</sup>.

The abundances of many elements, for example, lead, bismuth, tellurium, mercury, thallium, iodine, cadmium, zinc, germanium, uranium, thorium, in ordinary chondrites and to a lesser extent in enstatite chondrites depart widely from estimated 'cosmic' abundances, derived from nucleide systematics and theories of nucleosynthesis. On the other hand it is extremely significant that the Type I carbonaceous chondrite abundances are in reasonable agreement with the cosmic abundances for all but the most volatile elements<sup>1,3,8,9</sup>. This indicates that Type I carbonaceous chondrites have had a simpler chemical history than other classes of chondrites. This is supported by their highly oxidized state and by the high content of water, carbonaceous compounds and other volatiles which they contain. Letimer<sup>10</sup> and Urey<sup>11</sup> have pointed out that in the cold gas-dust cloud believed to be the immediate parent of the solar system, the dust particles would also be highly oxidized, volatile-rich, and composed of most elements in their primordial abundances. Accordingly Urey<sup>12</sup> suggested that the carbonaceous chondrites might be closely related to the primitive dust of the solar

nebula. This suggestion was developed in greater detail by Mason<sup>13</sup> and by me<sup>14</sup>. Although Type I carbonaceous chondrites appear to represent the closest approach to the primordial dust which we possess, it is probable that important differences exist. They appear to have had a mild thermal and metamorphic history and to have undergone slight differentiation. This may have occurred when the primordial dust accumulated into a small parent body.

From the relationships described here, it might be suggested as a working hypothesis that other groups of chondrites have evolved in some way from primitive material resembling the present Type I carbonaceous chondrites<sup>12,14,22</sup>.

## Oxidation-reduction Equilibria in Chondrites

From a critical study of the chemistry of chondrites Prior<sup>15</sup> concluded: "The less the amount of nickel-iron in chondritic stones the richer it is in nickel and the richer in iron are the magnesium silicates". This generalization has become known as Prior's rule, and is illustrated in Fig. 1 which is based on self-consistent chemical and mineralogical analyses. Fig. 1 shows that there can be no doubt about the validity of Prior's rule if it is taken as implying a general trend rather than a strictly quantitative relationship. As the amount of oxidized iron increases from 0 to 26 per cent, metallic iron falls from 30 to 0 per cent. A wide range in oxidation states (as defined by the  $\text{FeO}/\text{FeO} + \text{MgO}$  ratios of the silicates) is found. However, the range is not continuous. There is a large hiatus between enstatite and ordinary *H* chondrites<sup>14</sup>. More extensive investigations<sup>16,17</sup> indicate the presence of a small but distinct hiatus in  $\text{FeO}/\text{FeO} + \text{MgO}$  ratios between *H* and *L* groups. Keil and Fredriksson<sup>17</sup> concluded that Prior's rule is best used to describe and interpret redox relations between groups of chondrites rather than within individual groups. They make a strong case for this view when applied to the ordinary *H* chondrites. The metal contents within this group are not related closely to the  $\text{FeO}/\text{FeO} + \text{MgO}$  ratios of the silicates. It appears that the metal has become slightly fractionated independently of the silicates as in enstatite chondrites (Fig. 1). The situation with regard to the *L* group is not so clear. There has evidently been an analogous slight independent fractionation of metal for oxidized iron contents between 9 and 12 per cent. However, a distinct correlation of metal content with oxidized iron is present over the entire 9–16 per cent interval.

Urey and Craig<sup>8</sup> observed that the ordinary chondrites may be divided into two groups, *H* and *L*, according to their total iron content. The *L* group contains about 5 per cent less iron than the *H* group. This is shown clearly in Fig. 1, which suggests that the *L* group has been formed by the removal of about 5 per cent of metallic iron from the *H* group. It is therefore clear, as emphasized by Urey and Craig<sup>8</sup>, that the relationships between chondrites cannot be explained by a rigorous application of Prior's rule. In addition to variable redox states at constant total iron composition, some process for independent fractionation of metal must have operated<sup>14</sup>. This is also seen to have occurred in the enstatite chondrites (Fig. 1). Nevertheless, this complexity should not be permitted to divert attention from the importance of Prior's rule viewed as a general trend rather than as a rigorous relationship.

In the previous section it was concluded that the parental material of the chondrites was highly oxidized. It follows from the relationships described by Prior, and already discussed here, that the oxidized primitive material was subjected to widely varying degrees of chemical reduction. The two most abundant reducing agents are hydrogen and carbon and it is of vital importance to establish which of these dominated in the chondrite reduction processes.

Decisive evidence is supplied by the enstatite chondrites. The metal phases of these objects contain several per cent of elemental silicon in solid solution<sup>18</sup> and the FeO content of the silicates is of the order of 0.1 per cent<sup>19</sup>. These observations establish that enstatite chondrites formed under extremely reducing conditions. If they formed by a process of hydrogen reduction or by condensation of a hydrogen-rich gas phase, a very high hydrogen-to-oxygen ratio is required. Thermodynamic calculations indicate required minimum H/O ratios at appropriate temperatures varying between 300 and 2,000 (refs. 20, 21 and 22). For comparison, the H/O ratio of the solar atmosphere is about 1,000.

It is very difficult to understand the occurrence of sulphur, zinc, cadmium and carbon in enstatite chondrites if they formed under these conditions. Graphite is a significant constituent of most enstatite chondrites. However, it is completely unstable in the presence of excess hydrogen and/or oxygen at elevated temperatures. With the solar H—O—C abundances, carbon would occur as CO or CH<sub>4</sub> dependent on pressure. Enstatite chondrites also contain on the average about 3 per cent of sulphur occurring mainly in FeS. At 1,500° C the equilibrium  $\text{FeS} + \text{H}_2 = \text{Fe} + \text{H}_2\text{S}$  proceeds to the right when the H/S ratio exceeds about 70. The solar H/S ratio is 50,000 which is 700 times higher than will permit the stability of FeS or any other sulphide phase with equivalent sulphur activity. Analogous arguments apply to zinc and cadmium which are present in some enstatite chondrites in the same proportions as in Type I carbonaceous chondrites, that is, in their 'cosmic' abundances. It is impossible to condense or retain these volatile elements

in the presence of solar H—O—S abundances at temperatures above 1,000° C (ref. 7).

On the other hand, the retention of carbon, sulphur, zinc and cadmium is explicable if the redox state of enstatite chondrites was established through reduction by carbon rather than hydrogen. Minerals occurring in enstatite chondrites are schreibersite, (FeNi)<sub>3</sub>P; daubréelite, FeCr<sub>2</sub>S<sub>4</sub>; oldhamite, CaS; troilite, FeS; osbornite, TiN; graphite and iron silicide. All these minerals are characteristic of blast-furnace assemblages produced when iron ores are strongly reduced by carbon. The common occurrence of this group of minerals in both environments strongly suggests that the chemical processes which produced enstatite chondrites and blast-furnace irons have been similar, that is, that the iron in meteorites has been produced by reduction in a condensed system in the presence of carbon<sup>14,23</sup>. It may be noted that in such a system, in the presence of an appreciable pressure of sulphur, but at low hydrogen pressure, zinc and cadmium are stable at high temperatures as sulphides.

It is concluded that the mineral assemblage and chemical composition of enstatite chondrites cannot be accounted for either by reduction of primitive material by hydrogen or by condensation from a hydrogen-rich gas phase. On the other hand, formation by carbon-reduction of primitive oxidized material in a condensed system at high temperatures is consistent with the observations. In view of the clear genetic relationships between enstatite and ordinary chondrites, it is probable that the latter have been produced by a similar process. Further direct evidence for the production of nickel-iron and silicon-iron in the Kaba Type III carbonaceous chondrite and the Grady ordinary chondrite by carbon reduction has been described by Sztrókay *et al.*<sup>24</sup> and Ramdohr<sup>25</sup>.

### Origin

The foregoing arguments lead to the basic hypothesis that ordinary and enstatite chondrites have formed by autoreduction from primitive material similar to the Type I carbonaceous chondrites<sup>8,13,14,26</sup>. It must be admitted, however, that the physical and chemical conditions under which this autoreduction may have occurred are very poorly known and consequently the subject of much controversy. One of the principal unsolved problems concerns the mechanism by which the fractionations of elements between the principal groups occurred. Another basic problem concerns the identification of the parent bodies of the chondrites. Most evidence suggests that they are formed by collisions in the asteroidal belt<sup>8</sup>. However, from the short cosmic-ray exposure ages of chondrites, Urey<sup>27,28</sup> has argued in favour of an origin on the lunar surface. Evidence at present available does not permit a clear choice between these sources. Accordingly, it is appropriate to consider alternative models of origin.

(a) *Asteroidal Model.* The following model is a modification of an earlier hypothesis of mine<sup>8,14,29</sup>. Aspects of this hypothesis were criticized by Mueller<sup>30</sup> and Anders<sup>9</sup>, and the modifications have been introduced to meet these objections.

It is assumed that chondrites evolved on parent bodies in the asteroidal belt which formed by direct accretion from the primitive oxidized dust phase of the parental solar nebula. The composition of these bodies was similar to Type I carbonaceous chondrites. They were heated internally by short-lived radioactivities<sup>31</sup>, resulting in the reduction of oxidized iron by carbonaceous compounds, to produce a metal phase *in situ*, and in equilibrium with the surrounding silicates. Most of the reduction proceeded under sub-solidus conditions, and the gaseous reduction products were able to migrate to the surface of the parent body, where they escaped. In the early stages of reduction they consisted principally of CO, and H<sub>2</sub>O, while in the later stages, CO and H<sub>2</sub> predominated. In the case of the ordinary chondrites, reduction

Fig. 1. Relationship between oxidized iron and metallic iron for chondrites characterized by self-consistent chemical and mineralogical FeO/FeO + MgO determinations. Adapted from ref. 14

proceeded until almost all the carbonaceous material had been consumed. The varying oxidation states of the ordinary chondrites are thus explained in terms of varying initial quantities of hydrocarbons trapped in the accreting dust. In the case of enstatite chondrites, carbonaceous compounds were in excess. Accordingly, reduction of iron to metal was complete and reduction proceeded sufficiently far to produce some elemental silicon. The enstatite chondrites contain graphite in accordance with this model.

With further heating, extensive melting occurred in the deep interior of the parent body or bodies. Turbulence generally prevented settling of unmelted metal particles and silicate crystals. However, in the parent body of the *L* group, turbulence was not sufficient to prevent a limited amount of fractionation caused by sinking and segregation of metal particles in the magma, and resulting in the depleted metal content characteristic of this group. The magma rose to the surface regions of the parent body. Decrease of confining pressure in the surface regions permitted reaction of residual carbon to proceed to completion. Rapid escape of gaseous reduction products (mainly CO and H<sub>2</sub>) from the magma at this stage caused disruption and resulted in a type of volcanism, leading to the formation of chondrules and the development of typical chondritic structures.

The conversion of a Type I carbonaceous chondrite into an ordinary chondrite by the above process involves the loss of about 30 per cent of the initial mass as volatile components—principally H<sub>2</sub>O, CO, H<sub>2</sub>S, CO and H<sub>2</sub>. These are lost continuously as dense, supercritical fluids, during heating and reduction. The composition of these fluids varies according to the stage of reduction. It is possible that the migrating fluids functioned as powerful selective solvents for many minor elements and that extensive chemical fractionations were thereby caused. Thus, loss of chalcophile elements from ordinary chondrites may have been caused by their solubility as complex hydrosulphide ions in H<sub>2</sub>O—H<sub>2</sub>S—H<sub>2</sub>S solutions<sup>1</sup>. A lower hydrogen fugacity in the parent body of enstatite chondrites may have prevented the formation of these soluble complex ions and accordingly the chalcophile elements were not lost<sup>1</sup>. Fractionation of oxyphile elements, for example alkaline earths and rare earths, may have been caused by solubility in H<sub>2</sub>O—CO<sub>2</sub> solutions given off at an early stage of reduction<sup>1,7</sup>.

The processes postulated as explanations of the fractionation patterns in chondrites are poorly understood and incomplete. One thing, however, is certain. The loss of 30 per cent of volatile components during auto-reduction of Type I carbonaceous chondrite material at elevated temperatures and pressures must inevitably cause extensive selective fractionations of many elements. Whether or not these fractionations correspond with those observed in ordinary and enstatite chondrites remains to be determined.

(b) *Lunar model.* The case for a lunar origin of chondrites rests largely on interpretation of their short cosmic ray exposure ages<sup>11,17</sup>. I have suggested elsewhere that the Moon contains substantial amounts of material similar in composition to Type I carbonaceous chondrites<sup>22,26,31</sup>. It might therefore be suggested that this material has evolved into ordinary and enstatite chondrites by the operation of processes analogous to those advocated above for the asteroidal model. It would be necessary to assume the presence of short-lived radioactivities in the Moon soon after its formation.

In this section I wish to propose an alternative model for the formation of chondrites on the Moon. It is suggested that ordinary and enstatite chondrites may have formed from planetesimals of Type I carbonaceous chondrite composition by impact phenomena when the latter fell on the Moon during its final stages of formation. The impacts would cause transient heating, leading to

shock melting. It is possible that carbonaceous material reacted with oxidized iron under these conditions leading to formation of a metal phase. The accompanying explosive loss of reduction products may have disintegrated the shock-melted chondrite, forming chondrules in the manner demonstrated by Fredriksson and Ringwood<sup>22</sup>. The mixture of chondrules and metallic particles then became consolidated into chondrites on the lunar surface. These events all occurred about 4.5 billion years ago. More recently, collisions of asteroids and/or comets with the Moon ejected substantial amounts of chondritic material which was afterwards swept up by the Earth<sup>22,27</sup>.

This mechanism appears to satisfy the major requirement discussed previously that ordinary and enstatite chondrites formed from primitive material by a process of carbon reduction in a condensed environment. The transformation of a carbonaceous chondrite into an ordinary chondrite requires about 300–400 cal/g. This may be compared with the free fall energy at the Moon's surface of approximately 700 cal/g. It is possible that the energy liberated by impact of the planetesimal with the Moon may have been substantially higher than this, depending on its previous orbit.

A serious difficulty of this hypothesis lies in explaining the fractionations of elements among the different chondrite groups. Previously it was suggested that these were caused by selective solubility of various elements in supercritical, dense fluids of H<sub>2</sub>O, H<sub>2</sub>S, CO<sub>2</sub>, CO and H<sub>2</sub>, which were expelled during heating in the parent body. An analogous explanation might be attempted in the present case. The volatile components mentioned here must also be liberated over a very short time-interval as a dense fluid during the impact and reduction, and there will be a partition of many other elements between the chondritic and the fluid phases. The nature of the partition equilibria which would occur under such conditions is quite unknown, but almost certainly they will lead to substantial chemical fractionations of some sort. Whether they are in the required direction can only be established by experiment.

The foregoing hypothesis is admittedly highly speculative. However, if the essential features could be supported by subsequent direct experiments, the hypothesis may prove to possess certain advantages over other explanations of the origin of chondrites, for example: (1) It is not necessary to assume the presence of short-lived radioactivity in the parent bodies of chondrites. (2) It provides a ready explanation for the common occurrence in meteorites of structures caused by shock waves. These structures would be produced by impacts on the Moon. It is doubtful whether collisions between asteroidal parent bodies could cause the observed phenomena, since the relative collision velocities of objects in asteroidal orbits are usually smaller than 1 km/sec<sup>28</sup>. (3) It is easier to understand the formation of polymict meteorites by collision phenomena on the lunar surface than between asteroids. Because of the small gravitational potential energy of the latter, collisions are more likely to lead to disruption and loss of material than thorough mixing and consolidation. (4) The Moon was originally much closer to the Earth than at present. It is possible that the Earth's magnetic field was stronger early in its history and that it possessed appreciable strength at the distance of the lunar orbit. The remnant magnetization displayed by chondrites<sup>29</sup> might then have been obtained in the terrestrial field. (5) Present explanations<sup>3,24</sup> of the occurrence of primordial gases in meteorites attribute it to a mixture of two components. One component resembles that possessed by carbonaceous chondrites and is thus readily explained on the present model. The other component is of unfractionated solar composition. Fredriksson *et al.*<sup>22</sup> have shown that rare gases can be incorporated in mineral grains by shock wave phenomena. The final stages of accretion of the Moon may have

occurred before the unfractionated gases of the solar nebula had been dissipated. Shock-wave phenomena accompanying the collisions of carbonaceous chondrite planetesimals with the Moon in the presence of unfractionated solar gases may have led to incorporation of the observed gases in chondrites (and other meteorites).

The foregoing discussion has been concerned with chondrites. It is also possible that other classes of meteorites have also been formed on the Moon under conditions which permitted complete melting and extensive differentiation of chondritic material<sup>10</sup>.

### Conclusion

Neither of the two hypotheses discussed here is complete or satisfactory in all respects. However, I believe that they are faced by less numerous and less serious objections than apply to the currently popular hypothesis that chondrites have formed from material which condensed directly from a hydrogen-rich gas phase during the passage of shock waves through the solar nebula<sup>11</sup>. A critical discussion of this latter hypothesis will be presented elsewhere<sup>12</sup>. Clearly it is of decisive importance to establish whether chondrites are derived from the Moon or from the asteroids. Until an answer to this question is forthcoming, great uncertainty surrounds all theories of origin, although many important boundary conditions have been revealed through recent chemical and physical investigations.

## LATE WEICHSELIAN GLACIATION IN THE CHESHIRE-SHROPSHIRE BASIN

By G. S. BOULTON and P. WORSLEY

Department of Geology, University of Keele, and Department of Geography, University of Manchester

SINCE Hull's<sup>1</sup> recognition of a tripartite sequence in the Pleistocene deposits of the Oldham area in 1864, the succession Upper Boulder Clay, Middle Sands, Lower Boulder Clay has been accepted by many subsequent workers in the Cheshire-Shropshire Basin and the adjoining parts of Lancashire. Dissenters from this view, such as Kendall<sup>2</sup> and Marsh<sup>3</sup>, regarded the succession as much more complex. T. I. Pocock<sup>4</sup> considered that a Lower Boulder Clay ice sheet found its limit to the north-west of the Warwickshire Avon, that the Middle Sands were laid down as outwash deposits during the retreat of this ice sheet, and that the Upper Boulder Clay represented a re-advance to a moraine stretching from Market Drayton to Ellesmere. Poole and Whiteman<sup>5</sup>, however, considered this moraine to be a Middle Sands moraine deposited during the retreat of the Lower Boulder Clay ice sheet, and afterwards overridden by the Upper Boulder Clay ice sheet which terminated in the Birmingham area.

It is now clear that in the northern part of the Cheshire-Shropshire Basin the sequence is often very complex. Sections quoted by McQuillin<sup>6</sup> between Ashley and Wrenbury, and further north near Aldford, show up to five clay bands separated by sands and gravels. Pocock<sup>4</sup>, in the Macclesfield area, found three boulder clays beneath Middle Sands, while examination of borehole data together with detailed mapping, between Bar Hill and Wrexham, shows sequences similar to those found by McQuillin. Many sections show Poole and Whiteman's<sup>5</sup> conception of Pocock's<sup>4</sup> Market Drayton—Ellesmere moraine as a Middle Sands moraine overlain by Upper Boulder Clay to be a considerable oversimplification.

The succession exposed in the sand quarries of the Chelford area has been described by Simpson and West<sup>7</sup> as a type example of the tripartite sequence. A detailed investigation of the quarry sections and borehole records reveals the situation shown in Fig. 1.

Data derived from trial borings show no evidence of a Lower Boulder Clay lying beneath the sands. A Boulder Clay-Sand Complex, consisting predominantly of lens-shaped masses of tough red-brown till in intimate association with red-yellow sands, overlies a series of strongly cross-stratified, grey-yellow, poorly sorted pebbly sands containing abundant coal fragments, the cross-bedding indicating a northerly derivation. These deposits lie unconformably on sands which are very distinctive, and for which the authors would suggest the term 'Chelford

Fig. 1. Schematic diagram showing the sequence of drift deposits in the Chelford area.

Sands'. These Chelford Sands are characterized by a high degree of sorting (mechanical analyses on samples collected from single cross-strata show 95 per cent of the sample to lie between the 0.4-mm and 0.1-mm size grades) and high quartz content (87.4 per cent silica on chemical analysis). Low angle cross-stratification (up to 15°), tabular planar sets defined by plane beds, and minor distributory channels, indicate current flow from a source between north-east and south-east. Within the sands are many intraformational frost cracks up to 8 ft. in depth, and occasional dreikanter. The evidence suggests a depositional environment of low angle alluvial fans subject to occasional sheet flooding, in a cold arid climate. Locally the uppermost 10 ft. of the Chelford Sands are a buff colour due to iron staining; but this is progressively cut out by the unconformity. Several lens-shaped organic beds occur in the Chelford Sands, flat-lying tree trunks within them having a roughly north-east-south-west orientation. These beds, dated at 57,000 years B.P., give an upper age limit to the overlying glacial complex.

The examples quoted above, together with many other such complex sequences now known from the Cheshire-Shropshire Basin, throw doubt on the validity of the terms Upper Boulder Clay, Middle Sands, and Lower Boulder Clay as meaningful lithostratigraphic units. Boulder clays lying at surface on sands have in the past been automatically referred to the Upper Boulder Clay although, as McQuillin's<sup>6</sup> sections show, they may not be correlative. Similarly, the Chelford sections show the yellow-grey sands to be stratigraphically different from the underlying Chelford Sands, although both have been referred to as Middle Sands.

This often complex and thick sequence appears, however, to have a southerly limit in a ridge of high ground stretching in two arcs from Bar Hill to Whitechurch and Wrexham. Detailed mapping along the line of this ridge shows it to be a complex end-moraine.

It rises up to 150 ft. above the level of the surrounding country and is as much as 2 miles wide. At the eastern end, between Bar Hill and Adderley, large numbers of minor ridges are superimposed on the moraine and aligned in a north-east-south-west direction. These smaller ridges are often cut through, or flanked by, deep channels, and enclosed peat-filled kettles are prominent. Immediately east of Whitechurch the moraine is a very sharp ridge, and in the Ellesmere district it forms the southern limit to a broad area of hummocky 'stagnation' topography. The moraine is often broken through by valleys which are presumably melt water channels derived from the retreating ice, the form of the moraine indicating that the ice-front was bi-lobate in form, the ice being divided by the Mid-Cheshire Ridge (Fig. 2). Belts of hummocky terrain, running north-south along the eastern and western margins of the Basin, are continuous with the end-moraine, and it seems that these, together with deposits such as the Wrexham Delta Terrace<sup>6</sup>, were marginal or sub-marginal accumulations built up at an ice-front which lapped against the flanking hills. Indeed the deposits at Llay, described by Peake<sup>8</sup> as laid down by a further re-advance along the Welsh borders, appear to be an integral part of this marginal complex.

Many of the deposits lying north of the end-moraine appear to retain their original depositional forms. This is best seen in the hummocky 'stagnation' topography of Ellesmere, Padeswood, Wrinnehill and other areas. The present-day surface topography seems, over much of the area, to be similar to that which must have existed immediately subsequent to deglaciation, the different surface deposits in different places being due to the varying conditions of deposition within a single ice-sheet.

The boulder clays and related deposits to the south of the moraine are generally thinner and considerably more eroded than those to the north, often showing evidence of considerable solifluxion; depositional forms are rare. A similar contrast between the drifts north and south of the

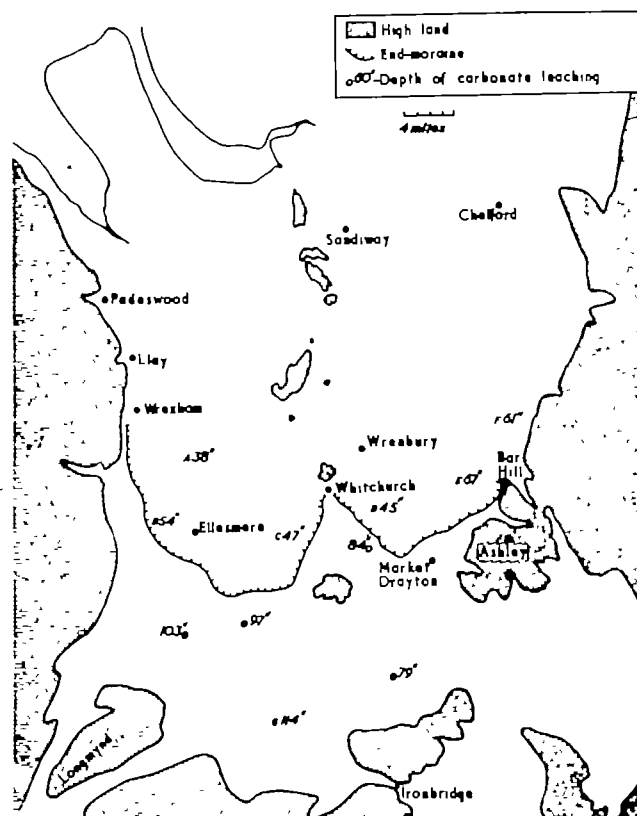

Fig. 2. The Bar Hill-Whitechurch-Wrexham moraine figures at localities A, B, C, D, E, F and G represent the mean of several leaching measurements taken from that general area. Figures marked O represent measurements taken from one locality only.

A, 4 results; B, 6 results; C, 11 results; D, 12 results; E, 7 results; F, 14 results; G, 5 results.

Brandenburg-Leenow moraines of the North European Plain is the basis of the Weichselian/Warthe distinction<sup>10</sup>.

The boulder clays which cap the end-moraine often appear to merge with those to the south. It may, however, be possible to distinguish between them by considering the depth of leaching in these deposits, which is a function of several variables—permeability, carbonate content, topography, climate and time. Depths of carbonate leaching in boulder clays of similar lithology at localities of similar topographic position, both north and south of the Bar Hill-Whitechurch-Wrexham moraine, were calculated, a correction for variation in original carbonate content being made using the equation<sup>11</sup>:

$$k \text{ (original thickness)} = \frac{100 \times d \text{ (measured thickness of leached profile)}}{n \text{ (\% of non-carbonate in unleached specimen)}}$$

The results are marked on the map (Fig. 2). 54 measurements north of the moraine gave a mean depth of leaching of 53 in. As yet only a few measurements have been made south of the moraine but the depth of leaching appears to be significantly different, the mean of 9 measurements being 104 in. This suggests that the surficial drifts north and south of the moraine do not belong to the same drift sheet, but that the drifts to the south are considerably older than those to the north. It would, therefore, appear that the ice-sheet which was responsible for the deposition of an Upper Boulder Clay in the northern part of the area advanced to a line extending from Bar Hill to Whitechurch and Wrexham, in which position an end-moraine accumulated. The ice then retreated and did not afterwards override this moraine.

Although morphologically the Bar Hill-Whitechurch-Wrexham advance is a well-defined unit, it is extremely difficult to determine the vertical extent of the deposits belonging to it. The apparent complex sequence of

deposits in this area invalidates the facile assumption that boulder clay = glaciation, and that sands = retreat deposits. Indeed, where the tripartite succession appears to hold, as in the Stockport area<sup>10</sup>, there is no evidence of a break or a weathering horizon in the sequence to indicate a time gap between two major glaciations, and the fact that Upper Boulder Clay and Lower Boulder Clay are lithologically identical is an argument against a two-glaciation explanation. Moreover, Upper Boulder Clay is often seen to overlie sand in which there is no trace of disturbance. Thus, as yet there is no definite evidence of deposits of a glacial advance above the horizon of the Chelford Sands and below the deposits which appear to belong to the Bar Hill-Whitchurch-Wrexham advance, which it is now possible to date.

Abundant molluscan shells, presumably derived from the Irish Sea, are contained within the Cheshire drift sequence. Shells obtained from coarse sands at the base of a till/sand complex (which has been referred to the Upper Boulder Clay), exposed in a pit at Sandiway near Northwich, have been dated by the radiocarbon method (Isotopes Inc., New Jersey). An assay on two specimens of *Nucella lapillus* (L.) gave an age of 28,000 years B.P. +1800, -1500. The shells were complete, relatively unleached and each about 20 g in weight; much of the outer shell was leached away by acid treatment prior to the assay, to minimize the effect of contamination.

On the latest data available from Europe<sup>11</sup>, there appears to have been a widespread climatic amelioration between 30,000 and 25,000 years B.P., known in Europe

as the Paudorf interstadial. This climatic amelioration was followed, in Europe and North America, by the maximum of the last or Weichselian glaciation. The dated molluscs, whatever their means of derivation, underlie and therefore pre-date a till/sand complex which has been correlated with the Upper Boulder Clay which terminates at the Bar Hill-Whitchurch-Wrexham moraine. Zone II organic deposits have been found lying upon this till sheet at Hatchmere (S.J. 555720) (J. W. Franks, personal communication). The Bar Hill-Whitchurch-Wrexham advance is, therefore, younger than 28,000 years B.P., and older than 10,000 years B.P. The most extensive glacial phase which falls between these two dates is the Late Weichselian glaciation which reached a maximum along the Brandenburg-Leanow moraines of North Europe at about 20,000 years B.P., and it is to this stage that the Bar Hill-Whitchurch-Wrexham advance must belong.

## LITHOFACIES AND CORRELATION WITHIN THE LOWER TORRIDONIAN

By D. E. LAWSON

Sedimentology Research Laboratory, Department of Geology, University of Reading

A STRIKING association of sedimentary units (Table 1) within the lower Torridonian Diabaig Group can be traced from Stoer to Rubha Réidh, Wester Ross (Figs. 2 and 3). Correlation is facilitated by three marker horizons which persist for up to 50 km: a tilloid, a limestone horizon, and an extraordinary sandstone-boulder conglomerate. In this report units 1-8 correspond to those established by the Geological Survey in the Diabaig Group at Stoer<sup>1</sup>.

At Coigach, Gracie<sup>2</sup>, mapping the area of Cnoc Mor an Rudha Bhig, sub-divided the lower Torridonian as follows:

- V Enard Bay 'shoreline'
  - (a) coarse-grained facies
  - (b) fine-grained facies
- IV sedimentary breccio-conglomerate facies
- III laminated sandstone facies
- II Loch na Seana-Chreig 'shoreline'
  - (a) coarse-grained facies
  - (b) structureless sandstone facies
  - (c) fine-grained facies
- I 'fanglomerate' facies

He recognized an unconformity beneath the sedimentary breccio-conglomerate facies and the 'probably contemporaneous' Enard Bay 'shoreline' (NO 028147, NO 033148). He also suggested a second unconformity at the base of the laminated sandstone facies (NO 027147).

Throughout the area (Fig. 2) the lower Torridonian unconformably overlies the Lewisian Gneiss. The succession (Table 1) begins with breccias and conglomerates (dominated by fragments of locally derived gneiss) and associated well sorted flaggy to laminated sandstones

(units 1-3). Their restricted occurrence, lithological variation, thickness and preservation are controlled largely by the pre-Torridonian gneiss topography. Sandstones of unit 4 are well exposed at Stoer (NO 034286 to 038283 and 037279 to 036273) and Badluhrach (NG 983957). Elsewhere they are of local occurrence or absent. The coarser sandstones display penecontemporaneous deformation structures and trough cross-beds. At

Table 1. UNITS WITHIN THE LOWER TORRIDONIAN

Unit	Occurrence	Approx. max. thck. (metres)
10. Flaggy to laminated sandstone with occasional shales.	Rubha Réidh	60 (Rubha Réidh)
9. Sandstone-boulder conglomerate	Coigach (V, a, b)* Coigach (IV)*, Badluhrach, Rubha Réidh, traces at Coigach, Loch Kerneary?	70 (Rubha Réidh)
8. Well laminated, cross-bedded sandstones	Stoer, Coigach (III)*, Coigach, Badluhrach, Rubha Réidh	486 (Coigach)
7. Red mudstones	Stoer, Coigach (II)*	50 (Stoer)
6. Sandstones and shales with thin beds of limestone	Stoer, Coigach (II)*	50 (Stoer)
5. Tilloid	Stoer, Coigach (II)*, Coigach, Badluhrach	43 (Coigach)
4. Coarse, red, occasionally contorted sandstones with interbedded mudstones	Stoer, Coigach (II)*, Badluhrach	300 (Stoer)
3. Gneiss conglomerate and breccia	Well developed in Stoer, occur locally from Coigach (I)* to Rubha Réidh	200 (Stoer)
2. Red, flaggy sandstone		
1. Gneiss conglomerate and breccia		

\* Refers to Gracie's divisions at Cnoc Mor an Rudha Bhig, Coigach<sup>2</sup>.

Fig. 1. Lower portion of the sandstone-boulder conglomerate at Badluchrach. Height of cliff 14 m

Badluchrach the troughs exceed 15 m in breadth. Sun-cracks and rippled surfaces occur in the interbedded red mudstones.

The first unit of correlative significance, the tilloid (as defined by Crowell<sup>12</sup>, cf. Pettijohn<sup>13</sup>), has been described in the Northwest Highlands memoir<sup>1</sup> as "a hard rib of sandy, calcareous mudstone with fragments of igneous rock" at Stoer; as "a breccia made up of igneous fragments, principally of epidiorite, at Badluchrach; and as "a dark purple grit deeply stained with ferric oxide, and composed of angular fragments of felsite and grains of quartz and feldspar" at Scoraig. At Coigach (NO 082146) the tilloid forms the lower portion of Gracie's IIB division.

Throughout the area the tilloid is characterized by abundant angular fragments of green, fine-grained igneous rocks, ranging up to 5 cm in maximum dimension, set in a subordinate red, muddy to sandy matrix. Fragments derived from the underlying sandstones and siltstones occur throughout, together with rare pebbles or cobbles of Lewisian rocks. The sharp, clear-cut basal contact is an erosional surface, broadly planar but with occasional minor relief (up to 2.5 m). The thickness of the tilloid at Stoer is 25 m, at Coigach 43 m and at Badluchrach approximately 20 m.

A remarkable feature of the tilloid at Stoer is the way in which parts of it laterally intrude and contort the strata of unit 4. Blocks of sandstone up to 2 m long, together with smaller fragments of mudstone, have been detached, transported and further deformed within the tilloid. Available evidence suggests that the tilloid is a volcanic mudflow with breccia-beds, and that it passes laterally into volcanic sandstones. Comparable deposits described by Crandell<sup>2</sup> are attributed to mudflows of volcanic origin.

Well-rounded 'sedimentary pebbles' up to 1 cm across, with strongly hematitized rims, were described by Gracie in his IIB division at Coigach. These have been found in the upper part of the tilloid at Stoer, embedded in a sandy matrix. They may be accretionary lapilli, or pisolites derived from a relict soil profile of uncertain location.

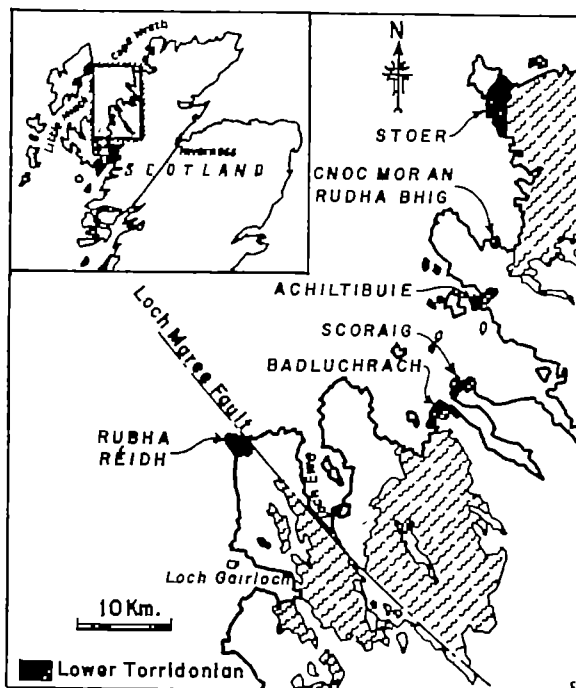

Fig. 2. Location of lower Torridonian outcrops referred to in the text

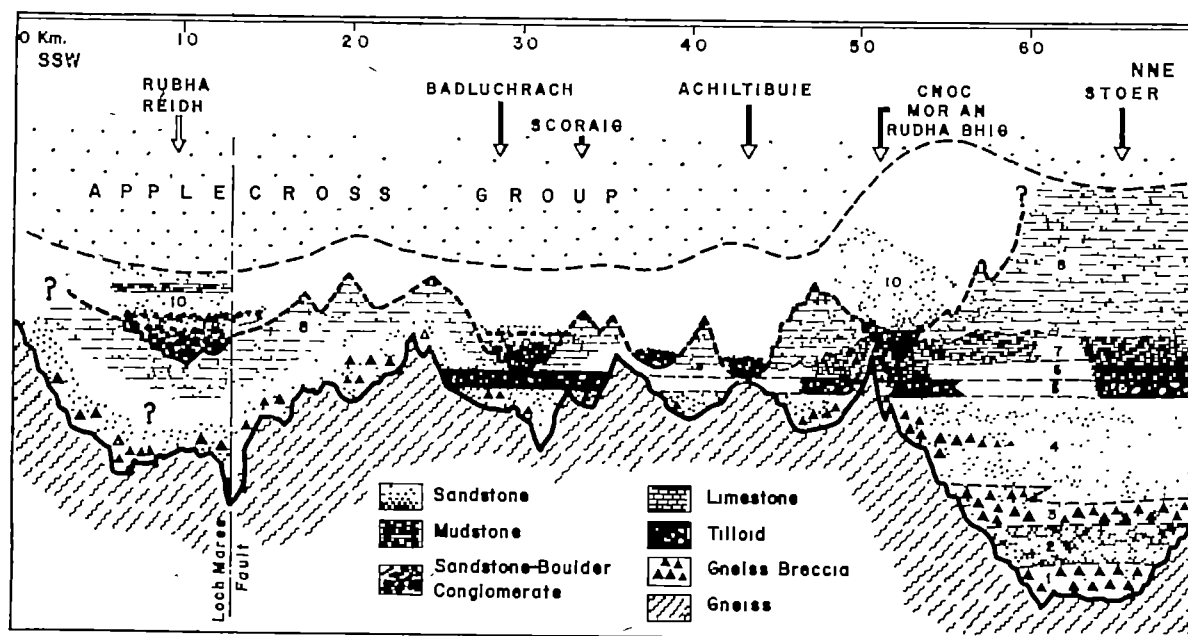

Fig. 3. Diagrammatic representation of present knowledge of distribution and relationship of units within the lower Torridonian. Vertical exaggeration  $\times 20$ . Loch Maree fault compensated for

Pisoliths of similar type commonly develop in present-day soils under alternating oxidizing and reducing conditions<sup>4</sup> and have been noted in piedmont soils developed from ferromagnesian-rich rocks<sup>5</sup>. This suggests an alternating wet-dry, warm climate at the time of deposition.

The limestone of unit 6 commonly comprises small (< 2 cm), grey, calcareous lentils and disrupted calcareous laminae within a red, silty matrix. At Coigach the limestone occurs in red, sandy mudstones (= the lower member of Gracie's IIc division) and laps on to the Lewisian-Torridonian unconformity, encrusting gneiss boulders. Microscopic textures suggesting algal activity have been found in the encrusting limestone by Miss E. R. Jamieson and these will be described elsewhere. At Stoer the base of unit 6 (lower 6 m) is mainly sandy, passing upwards into interbedded red sands and silts which form most of the unit. Two limestone beds totalling 104 cm in thickness occur approximately 12 m above the base, with grey siltstones and shales between, and for several metres above them. Graded beds occur at the top of the grey interval. Red mudstones interbedded with flaggy sandstones form the top of the unit, the flags showing sun cracks, ripple marks and pseudonodules. Above comes the uninterrupted sequence of red mudstones forming unit 7.

Well-developed thin stratification and frequent well-laminated cross-beds typify unit 8 wherever found. This new sedimentary style is initiated by a sharp erosional base at Stoer and Coigach. Lamination is regular and commonly planar or gently arcuate. Comparison with recent deposits<sup>6-8</sup> reveals a similarity to the lamination of intertidal and near-shore sandy sediments. In principle, however, a fluvial origin is also possible. Large-scale cross-bedding predominates in unit 8, with tabular and wedge-shaped sets of high or low dipping cross-laminae. Sets occur singly or in groups. The thickest known is 5.6 m (ref. 2); elsewhere maximum thicknesses are usually 1-2 m. Transport at Coigach appears to be from the east<sup>9</sup>, and at Badluhrach and Rubha Réidh from the north-east. These directions are contrary to those in the stratigraphically higher Applecross Group, which has been transported mainly from the west and north-west. Symmetrical and asymmetrical ripple marks are abundant at Rubha Réidh, their crests oriented predominantly north-east-south-west. These occur on beds between the cross-bedded units and are associated with sun cracks and some rainprints. At Stoer ripple marks are less frequent.

The sandstone-boulder conglomerate and spectacular unconformity beneath record a significant event in Torridonian depositional history hitherto recognized only in Coigach<sup>3</sup>. The Geological Survey reported the Badluhrach and Rubha Réidh unconformities, but assigned both conglomerates to the Trias<sup>10</sup>. The laminated sandstone (unit 8) and lower units are cut by a highly irregular steep erosion surface overlain by the conglomerate. At Rubha Réidh (NG 748922) a stepped contact cuts through 28 m of laminated sandstone in a horizontal distance of less than 40 m. With an average slope of 35° indented by steep steps with up to 5 m vertical relief, this exposure gives a convincing impression of an irregular cliffed shoreline buried beneath fallen debris of all shapes and sizes.

The lower unstratified portion of the conglomerate (up to 34 m thick) comprises a chaotic assemblage of sub-rounded to angular sandstone pebbles, cobbles, boulders and blocks (Fig. 1). The largest block measured 11 m × 4 m (ref. 2). The matrix (usually < 10 per cent of the rock by volume) consists of medium to coarse structureless sand enclosing occasional small fragments of vein quartz and granitic gneiss. No evidence was found of the 'Cambrian' pebbles previously reported at Rubha Réidh<sup>3</sup>. Pebbles of pale grey quartzite are found at Badluhrach but are not diagnostic of the Cambrian.

The sandstone fragments in the conglomerate are identical with the laminated sandstones beneath the unconformity. At Rubha Réidh isolated quartz veins and tension gashes are: (1) confined to the cobbles and boulders; (2) frequently oriented nearly perpendicular to the internal bedding. This implies sufficient time for the development of quartz veins during the interval between lithification of the laminated sandstone and subsequent erosion resulting in the unconformity. Predominantly vertical orientation of bedding in the large blocks and the quartz veining suggest that the conglomerate may have been derived from cliffs with strong vertical joints. Gracie<sup>3</sup> interpreted the conglomerate as a cliff rockslide deposit 'probably contemporaneous' with the sediments of his Enard Bay 'shoreline'.

In the upper portion of the conglomerate the fragments gradually decrease in size, a crude stratification appears, and the conglomerate becomes interbedded with sands progressively dominating the upper part of the sequence. These sands are well laminated, well sorted and display 'black bands' (predominantly iron ore minerals with traces of detrital epidote). The bands occur in zones 40-50 cm thick with individual concentrations ranging from 1 mm to 15 cm thick. The 15-cm bed at Rubha Réidh is exceptional and can be traced for more than 100 m. The black band zones occasionally show cross-beds and sag-and-drop structures (cf. Stewart<sup>11</sup>).

The sediments above the conglomerate are exposed only at Coigach and Rubha Réidh. At Coigach the conglomerate is transgressed by Enard Bay 'shoreline' sediments, separated from Applecross sandstone by an erosion surface. At Rubha Réidh the interbedded black band zones give way upwards to a considerable thickness of medium- to thin-bedded<sup>12</sup>, red (occasionally green) sandstones with cross-bedding, ripple marks and occasional thin concentrations of small (< 3 cm), well-rounded sandstone pebbles. These are overlain by 6-8 m of grey-green sandstones and sandy shales with large sun cracks and 'mud-with-lenticles lithology'<sup>13</sup>. Upwards the shales grade into red silts and sands by alternation. Coarse, pebbly, poorly sorted Applecross sandstones overlie the entire sequence with an irregular erosive contact.

The angular unconformity between the laminated sandstone and the Applecross east of Culkein Bay, Stoer (NG 042330), is marked by a sandstone-boulder conglomerate up to 1.3 m thick. Sub-rounded boulders of laminated sandstone (up to 1.2 m long) are set in a matrix of pebbly Applecross arkose<sup>14</sup>. Further work is necessary to determine the relationship of this conglomerate to the sandstone-boulder conglomerates of unit 9 to the south.

Definite changes in type of sedimentation at the bases of units 5, 8 and 9 separate the lower Torridonian into four major phases of deposition. The unconformity beneath the last phase (unit 9) may indicate a considerable lapse of time.

The assistance of Dr. A. J. Gracie and other colleagues in the Sedimentology Research Laboratory is gratefully acknowledged.

# PRIMARY SEDIMENTARY STRUCTURES FROM THE SILURIAN AND LOWER DEVONIAN OF THE OSLO REGION, NORWAY

By J. H. McD. WHITAKER

Department of Geology, University of Leicester

DURING a detailed investigation of the Silurian and Lower Devonian of the central and southern Oslo region, Norway, with special emphasis on the Ringerike area, various primary sedimentary structures have been found, most of which have not been described previously from this region. This article records their character and uses the evidence which they provide to deduce palaeocurrent trends and general conditions of deposition. A fuller account will be submitted for publication in the *Norsk Geologisk Tidsskrift*. For the stratigraphy and facies variations of the region, see Kjørstam<sup>1,2</sup> and Henningsmoen<sup>3</sup>.

In the Silurian, 'stages' 6, 7, 8 and 9 (mainly marine), four lithologies predominate:

(1) *Calcareous siltstones*, especially in 'stages' 6c (Llandoveryan) and 8a (Wenlockian), showing the greatest variety of structures. These include ripple mark, ripple bedding, ripple-drift lamination, small-scale cross-lamination, convolution, ball-and-pillow structure, slumps, rapid thickness variations, channelling, groove and striation casts, bounce, prod and roll casts, current-oriented fossils, load casting, diapirism, and trace fossils. Grading is generally absent but laminated tops occur. There is one penecontemporaneous discontinuity (erosion) surface.

(2) *Limestones*, especially in 'stages' 7a and 7b (Llandoveryan), 8c (Wenlockian) and 9 (Ludlovian), often shelly, showing thickness variations, channelling, cross-bedding, slumping, several types of nodular development, 'nodule lineation', small-scale reef structures, algal surrounds to other fossils, partially filled brachiopods acting as 'geological spirit levels' and fossil orientation including elliptical stromatoporoids.

(3) *Shales*, present in 'stages' 6, 7, 8 and 9, showing distortion of bedding around more-resistant objects such as limestone nodules, compression below groove casts, and flame structures where the overlying beds are load casted. They show mud cracks as early as 8b (ref. 4) and again at several horizons in 'stage' 9, with reddening. There are no macroscopic primary structures which are of use in palaeocurrent analysis.

(4) *Calcareous sandstones*, present in 6b and 8b, massive, often cross-bedded and slumped, and sometimes with ball-and-pillow structure.

In the highest Silurian and lowest Devonian, 'stage' 10 (mainly non-marine 'red-beds'), a further three lithologies are found:

(5) *Conglomerates*, with clay or limestone pebbles in a sandy matrix, often showing trough cross-bedding.

(6) *Sandstones*, micaceous, massive-bedded to thinly laminated, with ripple mark, ripple-drift lamination, tabular and trough cross-bedding, primary current lineation, load casting, ball-and-pillow structure, slumps, channelling, trace fossils (especially eurypterid tracks), flute casts (two examples only), a single rill mark and several problematical top-surface and sole markings.

(7) *Shales and mudstones* (relatively poorly developed except at the base) showing mud cracks (a few with diapiric structures<sup>4</sup>) and flame structures underneath load casts.

Palaeocurrent indicators are well developed at certain horizons and several hundred azimuths have been measured. The different types of directional structures give consistent results for the marine Silurian: the non-marine 'red-beds' of the Lower Devonian show, as might be expected, a different pattern of sediment distribution.

Most abundant in the Silurian are groove casts, widespread areally over a limited thickness of strata in 6c, between 7 and 18 m below the first prominent limestones, rich in *Pentamerus borealis* in 7a. Throughout the Ringerike area, shales a few cm thick alternate with calcareous siltstones of similar thickness, and on the soles of some of the siltstones are well-developed groove casts about 8 cm wide and 4 cm deep. They are generally fairly symmetrical in cross-section (Fig. 1) but some are slightly deformed by load casting. Superimposed on many of the groove casts, and having the same bearing, are striation casts, bounce casts and prod casts. Many show trace fossils as convex hyporeliefs<sup>4</sup>. Current-oriented slender polyzoa, tentaculites and accumulations of brachiopods, notably *Plagiorhyncha* (*Camartoechia*) *decomplicata*, have been found in the bottoms of the grooves, which are usually filled with finely laminated calcareous siltstones with inclined laminae, although shelly limestones are also found. Occasionally, disconnected 'rods' of siltstone are seen resting on, and covered by, shale, as at the cliff sections at Stein and Ultvedtåsen. This type may be referred to as 'separated groove casts' by analogy with the 'separated ripples' of Pettijohn and Potter (Plate 90)<sup>5</sup>. They are due to an insufficiency of silty filling to produce a connected bed. Burrowing organisms were active but bioturbation is not well developed. The trends of 249 grooves in 6c at Ringerike give a very pronounced maximum between east-north-east and east or west-south-west and west (arithmetic mean of bearings is 083° or 263°, standard deviation  $\pm 18^\circ$ ).

Similar large groove casts with associated striation casts at the same horizon may be seen along the roadside near Avles station on the Oslo-Kolsås line. On the south-west shore of the island of Mahøya in Oslofjord, 35 km south-east of Ringerike, normal and separated groove casts are again displayed (Fig. 2). Within them, oriented brachiopods and polyzoa occur. Here, the groove casts are slightly earlier (6b) than those just described, and the facies is more shaly, occupying part of the Oslo-Scania depression. In the Skien area, grooves similar to those at Ringerike occur. In these three more southerly areas, current trends are approximately north-east or south-west.

Other palaeocurrent indicators, much less common, include very small-scale cross-lamination and ripple-drift lamination, either in cosets rarely exceeding a few

Fig. 1. Normal groove casts in cross-section 6c, Harum, Ringerike. (Hammer handle is 8 cm wide)

Fig. 2. Separated groove casts in cross-section. 6b, Malmøya, Oslofjord. (Hammer handle is 30 cm long. Beds rotated to horizontal for comparison with Fig. 1)

centimetres in thickness, or as small 'dunelets' on the tops of calcareous siltstone beds. Kuenen<sup>8,9</sup> first commented on the presence of cross-laminated tops to graded greywackes and explained them as having been formed during the declining stage of a single turbidity current. Bouma<sup>10</sup> developed this idea, placing them in his "interval of current ripple lamination, *Tc*". Instead of greywackes, turbidity currents can lay down calcareous siltstones with similar structures, as in Cummins's Montgomery Trough<sup>11,12</sup>, and it is possible that the Oslo region Llandovery siltstones could be similar turbidites. A point of interest is that the dip of the foresets is not in the direction of the currents which produced the grooves, but approximately at right angles to them, directed southwards, a feature noted by Prentice<sup>13,14</sup> and Kelling<sup>15</sup>. Kelling suggested that the nose of a turbidity current sets up a lateral surge-wave which may be reflected back from the marginal slopes of a trough, the time-lag being such that transverse depositional structures are produced at the top of the turbidite. Evidence for such marginal slopes in the Ringerike area is given by measurements of 143 slump axes. The mean trend is 80°, standard deviation  $\pm 28^\circ$ , indicating northward or southward inclined palaeoslopes, again at right angles to the eroding current directions. It must be emphasized that while the sediments of 6b and 6c show some features characteristic of turbidites, the general absence of grading, rarity of convolution, lack of flute casts, the well-preserved shelly fossils and evident shallow-water conditions (described later) makes them far from typical. Perhaps Kuenen's<sup>8</sup> "diving flash floods" were the cause, initiated on barren lands without land vegetation. These flash floods, on entering water, would become "turbidites of zero depth"<sup>16</sup>, picking up shells from the near-shore zone, and these turbidites, being heavily charged with sediment, would tend to produce groove casts rather than flutes, filled with non-graded beds as there would be insufficient time for velocity-differentiation of the sediments<sup>17</sup>.

At higher horizons, directional structures are less common and groove casts are rare. At Ringerike, in 7a and 7b, elliptical stromatoporoids and 'nodule lineation' indicate currents from just north of east or south of west. In the silty beds of 8a there are occasional striation, prod and bounce casts and some ripple-drift lamination. On the west coast of the island of Store, Ringerike, a well-defined roll cast, made by a longitudinally ribbed orthoconic nautiloid, is associated with other sole markings, indicating movement towards the east. In 8a, there are alternating limestones and shales with large numbers of the lengthy coral *Semaiophyllum*. One hundred and eighty-seven bearings on long axes were measured and fairly good current orientation is indicated (mean trend 83° or 283°, standard deviation  $\pm 33^\circ$ ).

For 'stages' 6, 7 and 8, the results of palaeocurrent measurements give a consistent pattern of water movement from west-south-west or east-north-east at Ringerike, while farther south, on much less data, south-west or north-east directions are suggested. As on other evidence a source area (the Telemark Land which extends northwards into the Jotunheim) is postulated to the west, north-west and north of the Oslo region, these currents would more probably have been moving sediment in a west to east sense, rather than the reverse. A remarkable early paper by Küster<sup>18</sup>, who anticipated the use of palinspastic maps, shows troughs and uplifted areas along north-east and south-west directions during 'stage' 5 (high Ordovician) in the Asker area, south-west of Oslo. In this southern part of the region, but not in the centre, later folding was along the same axes. In the north of the Oslo region (Hadeland and Feiring), Major<sup>19</sup> measured the cross-bedding in the more sandy facies of the Llandovery and deduced derivation from the west and north. Henningsmoen<sup>2</sup> reports considerable transport of terrigenous material from north and north-west in lower Wenlock times. Thus, currents seem to have been converging on an area just north-east of Oslo.

The non-directional structures in 'stages' 6, 7 and 8 are common in many different environments and are of little help in indicating the conditions of deposition, except for: (1) the shelly limestones of 7a and 7b with stromatoporoids and corals, many on end or overturned, indicating clear water with considerable currents, and the larger reef structures of 8c, suggesting very shallow, well-aerated water; (2) rapid thickness variations and the formation of irregular, steep-sided channels in the limestones and calcareous siltstones especially in 6c over a wide area, suggesting rapid lithification and erosion by fast-moving currents; (3) also in 6c, the occurrence at Limåstangen of a uniquely eroded top to a calcareous siltstone which is standing above the general level of the bed at this locality (Fig. 3). The clint-like erosion surface continues below the overlying Llandovery shale, showing that it was formed immediately after deposition: this particular structure suggests local brief emergence above sea-level.

The evidence from both kinds of primary structures thus points to fairly shallow or very shallow water with vigorous normal currents and, at times, atypical turbidity currents flowing over most of the Oslo region in the Llandovery and Wenlockian, with a somewhat deeper trough over Oslo itself. The term 'miogeosyncline', used by some authors, is best avoided: the description 'shelf conditions' is preferable and draws attention to some similarities with the British Silurian shelf facies.

Twice there were departures from the normal conditions of sedimentation at Ringerike: during 7c (Upper Llan-

Fig. 3. Chert-like erosion surface on bed of calcareous siltstone. 6c, Lunde, Ringerike. (10 cm of the scale is visible)

doverian) marine mudstones of greyish red colour (10E 4/2 on the *Rock Color Chart*) were laid down, the pigment possibly derived from erosion of lateritic surfaces of basalts, and soon afterwards, several bentonites were deposited, as in Jämtland, Västergötland, Gotland and Scania, again testifying to widespread volcanicity towards the end of the Llandoveryan.

'Stage' 9 (top Wenlockian-Ludlovian) is more calcareous and suggests shallower conditions of deposition than the preceding 'stages' and there are few directional structures: measurements of the orientation of specimens of *Armenoceras* on adjacent bedding planes near Skjervold farm, Ringerike, give inconclusive results, and it would appear that, as in Britain at this time, the depositional trough was filling up and currents were more variable in direction. Small reefs with *Favosites* and stromatoporoids, *Amplexopora* meadows and other polyzoa surrounded with algal growths bear witness to shallow, lime-rich waters. From 9c onwards, occasional loss of typical marine conditions is shown by thinly bedded green shales with a fauna of eurypterids, phyllocarids, ostracoderms, small brachiopods, ostracods and the alga, *Chaetocladus*<sup>2</sup>. Several horizons show reddening and mud cracks, indicating temporary exposure to the atmosphere, a prelude to the succeeding 'stage' 10.

In the thick sequence of non-marine 'red beds' (the Ringerike Sandstone, 'stage' 10) the best-developed and commonest directional structure is cross-bedding. Less common is ripple-drift lamination (type 1 of Walker<sup>11</sup>), ripple mark and primary current lineation, a depositional structure recently discussed by Allen<sup>12</sup>. The dip directions

of 111 foreset beds, including some ripple-drift foresets, have been measured and the mean is 169°, standard deviation  $\pm 52^\circ$ , indicating sediments derived broadly from the north-north-west. Fifty-two slump fold axes give a mean trend of 72°, standard deviation  $\pm 27^\circ$ , suggesting a palaeoslope directed towards the south-south-east. This is consistent with a marked thinning (from 1,000 m to 800 m) in the Skien area to the south<sup>4</sup>. The clay and shelly limestone pebbles in the conglomerates indicate derivation most probably from the Silurian which lies to the north, while a more distant source in the same direction, namely, the uplifted Jotun nappes of Central Norway, is suggested by the presence in the sandstones of fresh anti-perthitic feldspars characteristic of the jotunites. Ripple mark and primary current lineation measurements are rather variable and no general pattern emerges.

The non-directional primary structures, notably mud cracks and animal tracks, indicate the periodic desiccation of bodies of water in which fish and eurypterids flourished. There is a large collection of tracks in the Palaeontological Museum in Oslo, including the spectacular tracks of the giant *Microporus* and the delicate markings made by very small eurypterids.

The results outlined here were obtained during the tenure of a post-doctoral fellowship awarded by the Royal Norwegian Council for Scientific and Industrial Research. I thank Dr. F. M. Broadhurst for his advice.

## HYDRATION OF PORTLAND CEMENT

IT was suggested earlier that the rate of hydration of individual minerals in Portland cement clinker depends on the position of Fermi-level in the individual minerals<sup>1</sup>. Furthermore, it has been shown that the reaction between Portland cement clinker and water is a semiconductor surface reaction, probably 'n' type reaction on 'p' type semiconductor<sup>2</sup>. Hydration of clinker minerals is, therefore, a chemisorption process occurring on the surface of clinker crystals (which may be semiconductors). Thus hydration (and similar reactions), in which Portland cement clinker takes part, should be controlled by the instantaneous position of Fermi-level in the minerals (see also ref. 3). It will be shown in this article that, as in the case of lime<sup>4</sup>, the lower the temperature at which thermionic emission starts from clinker minerals, the higher is its reactivity with water. This means that the

higher the position of the Fermi-level in clinker crystals the greater is the reactivity of the clinker with water. Thus the position of Fermi-level in clinker minerals controls the rate of hydration of Portland cement. This is in agreement with the theories put forward earlier<sup>1</sup>.

Experiments were carried out with the same cement clinker used in earlier experiments<sup>5</sup>. The clinker was powdered and the fraction passing a B.S. 300 mesh sieve was used once it had been freed of lime by repeated washing with absolute alcohol. Specimens used were (a) clinker, (b) clinker heated at 1,000° C for 4 h, (c) clinker heated with admixture of 1 per cent by weight, individually, of the following oxides: zinc oxide, chromic sesquioxide, oxides of molybdenum and manganese and lime and nickel oxide (the molybdenum oxide was obtained by heating ammonium molybdate, and the manganese

oxide by heating manganese acetate). Both heated and unheated materials were prepared in tablet form under pressure and the variation of electrical resistance of these tablets with temperature (in steps of 25° to 950° C) was measured, during heating and cooling, according to a method given elsewhere<sup>1</sup>.

Tablets were hydrated in water vapour for 3 days and then immersed in water for 7 days. Results of hydration have already been published<sup>2</sup> and these are made use of in this article (Table 1). Variation of resistance with temperature for the hydrated tablets, during heating and cooling, was measured in a similar manner.

Because the tablets cracked to different extents on heating and because the springs used to hold the samples quite often failed at high temperature, the resistance values obtained during cooling do not represent true values for the clinkers or of their hydrated products. Hence resistances of both anhydrous and hydrated materials only during heating are considered. In Fig. 1, only resistance-temperature ( $\log_{10} R \sim 10^4/T$ , where  $R$  is in ohms and  $T$  in degrees Kelvin) curves for anhydrous clinker and its hydrated product are shown. The curves for other materials are similar except that some of the kinks in the curves, which are attributable to phase changes, are either absent or suppressed to some degree in the heated samples.

In the resistance-temperature curve of each material there is an inflexion point, at which there is a sudden change in the slope (point A in Fig. 1). This change cannot be attributed to any phase change, as any such change does not occur at the temperatures corresponding to the inflexion point temperatures. The change in the slope of the curve is in the direction in which there is an increase in the electrical conductivity of the material. The temperature corresponding to this inflexion point is taken, on the basis of the arguments given in the earlier article dealing with lime<sup>4</sup>, to be the temperature at which thermionic emission starts from the material. Temperatures corresponding to inflexion points are given in Table 1. The points B and C (Fig. 1) may be due to phase changes

Fig. 1.  $\log_{10} R \sim 10^4/T$  plots (during heating). A and B are the plots for anhydrous and hydrated clinker (untreated) respectively

Fig. 2. Gain in weight of clinker samples due to hydration versus corresponding temperature of inflexion

occurring at these temperatures possibly in dicalcium silicate.

It can be seen (Table 1) that the temperatures at which the inflexions occur in the resistance-temperature curves are higher (except for ZnO and Cr<sub>2</sub>O<sub>3</sub>) than in the curve for the original clinker. The higher the inflexion-point temperature, that is, the higher the temperature at which thermionic emission starts, the lower is the Fermi-level. Thus with the clinker minerals (devoid of CaO<sup>1</sup>), the rate of hydration should decrease when heated alone or when heated with oxides of molybdenum, manganese, cobalt and nickel.

The temperature at which the inflexion occurs for the hydrated material (which had only partially hydrated) in all cases remains practically the same. It is higher than the inflexion point temperature obtained for corresponding anhydrous material except for the oxides of molybdenum and manganese. A rise in the inflexion point temperature (the rise in the temperature at which thermionic emission commences) may mean that the hydrated material is more of a 'p' type semiconductor than the anhydrous clinker. In the samples with the oxides of molybdenum and manganese it is the reverse, and the hydrated material appears to have become comparatively more of an 'n' type semiconductor.

The gain in weight of the different clinker samples due to hydration in the given time (three days vapour hydration, seven days water hydration) is plotted in Fig. 2 against corresponding temperatures of inflexion given in Table 1. The points are widely scattered, which is to be expected when one considers the inhomogeneous state of the samples, and that the effect of any of the oxides may not be identical for all the constituent minerals of the clinker. Nevertheless, there is a distinct tendency for the points to be in a band in which the gain in weight increases as the temperature of inflexion decreases. That is, as the temperature at which thermionic emission commences for the minerals is lowered, the gain in weight due to hydration in a given time—that is, the rate of hydration—increases. Any lowering of the temperature at which

thermionic emission starts means that the Fermi-level is raised (it comes nearer to the level just outside the crystal). It is therefore concluded that the higher the position of the Fermi-level in the clinker crystals the greater is their rate of hydration. Thus it is the position of Fermi-level in the Portland cement clinker minerals which controls their rate of hydration. The reason for this, in a mixture of minerals such as Portland cement, is now being investigated.

IN this article we shall consider the relationships controlling the hydration of Portland cement.

The amount of hydration of Portland cement in a given time was determined from the non-evaporable water content in the hydrated cement or from the water absorbed during hydration. The rate of hydration has been taken to be synonymous with the rate of growth of the hydrated products. From the results obtained and from the data given in the literature it is concluded that (a) during the early period of hydration (0.5–5 h) the relation between the quantity of water taken up by cement (water of hydration) and the time of hydration cannot be unequivocally assigned to any particular law—some data can be made to fit directly to a logarithmic law, others to an inverse logarithmic law and others to an inverse mass law; (b) thereafter, to a period of 28 days (the period over which observations were taken), hydration follows directly according to a logarithmic law. It has also been found that minor additions of cuprous oxide, zinc oxide and alumina to Portland cement enhance the rate of hydration, while traces of ferric oxide, chromic sesquioxide, nickel oxide and oxide of manganese retard it. The direct logarithmic law is, however, adhered to in all these cases. The oxidation rate of metals also obeys (among others) this direct logarithmic law. It should be pointed out that the reason for a similar law controlling the rate of hydration of Portland cement and rate of oxidation of metals may be due to the similarity in the basic mechanisms of the two phenomena. It is further suggested that the ions liberated during hydration of cement and the degree of stability of the water structure may also be factors influencing the rate of hydration of cement.

The results are arranged according to the following time schedule: (a) First 0.5–5 h of hydration (our own data); (b) 4–31 h of hydration (data taken from Fulton<sup>1</sup>); (c) 1–7 days of hydration (data taken from Fulton<sup>1</sup>); (d) 1–28 days of hydration, with or without admixture of oxides (our own data).

(a) *Period 1.5–5 h.* These experiments were carried out in two sets. In one, normal Portland cement was used as such, and in the other the same cement was heated for 18 h at 110° C and then used for hydration. 2 g cement was used in each experiment and this was mixed with distilled water (water cement ratio 0.40 by weight). Mixing was by hand for 3 min—this period being included in the hydration time. The mixtures were placed over water in a closed vessel for the periods

Fig. 1. Non-evaporable water content  $W \sim \log t$  ( $t$  in sec) for period 0.5–5 h. A  $W \sim \log t$ ; B,  $1/W \sim \log t$ .  $\circ$ ,  $\circ$ , unheated;  $\bullet$ ,  $\Delta$ , heated

27, 57, 117, 177, 237 and 297 min. Operations were carried out in a constant temperature room ( $\sim 78^\circ$  F). Materials were then placed in an oven and dried at 110° C to constant weight and the difference in weight of the dried sample and the original cement was taken as the non-evaporable water<sup>1</sup>—representing amount of water taken in hydration. Results are given in Table 1 and Fig. 1.

Gain in weight due to hydration per g of cement during a given time ( $W$  in mg/g) and its reciprocal are plotted against  $\log t$  ( $t$  in sec) and are shown as curves A and B, Fig. 1. A linear relation is obtained and a change in the slope of the curves is obtained after about 2 h hydration. The curve for  $1/W$  versus time is not shown, but it can easily be seen that a linear relation holds in this case also. Thus some data fit into a direct logarithmic relationship (curve A, Fig. 1), others an inverse logarithmic relationship (curve B, Fig. 1), and others inverse mass relationship. Hydration in this period (or in any of the subsequent periods) does not follow parabolic or cubic laws such as are found to hold good in oxidation of metals.

(b) *Period 4–31 h.* Data for water absorbed (mg/g) by cement when allowed to hydrate over this period, as given in Fulton<sup>1</sup>, are plotted against  $\log t$  ( $t$  in sec) (Fig. 2). Cements from 6 different sources were used in these experiments ( $H_1$ ,  $K_1$ ,  $L_1$ ,  $F_1$ ,  $M_1$  and  $N_1$ ). Data obtained with cements  $M_1$ ,  $H_1$  and  $F_1$  fall on a straight line. Inverse logarithmic and inverse mass relations were not obtained for this period. From Fig. 2 it can be seen that a sharp increase in the rate of hydration in these cements occurs after approximately 5.5–7 h. After this period the hydration continues at the same rate, for a given cement, for a period up to 31 h.

(c) *Period 1–7 days.* Treating Fulton's data for this period<sup>1</sup> in a similar way produced a linear relationship (Fig. 3) for plots of non-evaporable water content (mg/g) of hydrated cement against  $\log t$  ( $t$  in sec). (Cement had been taken from a number of sources, designated as  $R_1$ ,  $G_1$ ,  $O_1$  and  $F_1$ , and hydrated for periods 1–7 days.) Other relations do not hold good during this period.

(d) *Period 1–28 days.* Experiments were carried out using ordinary Portland cement as well as Portland cement mixed with 0.01 per cent by weight of cuprous oxide, zinc oxide, alumina and nickel oxide, and with 0.1 per cent by weight of ferric oxide, chromic sesquioxide

Table 1

Time (h)	0.5		1		2		3		4		5	
	W mg/g	1/W	W mg/g	1/W	W mg/g	1/W	W mg/g	1/W	W mg/g	1/W	W mg/g	1/W
Pure cement	5.50	0.182	6.60	0.152	8.10	0.124	12.30	0.081	18.06	0.056	23.4	0.043
Cement heated	6.70	0.149	7.10	0.141	9.40	0.106	13.20	0.076	17.00	0.059	24.2	0.041
Log t (sec)	7.4956		8.1887		8.8819		9.2873		9.5749		9.7981	

and oxide of manganese (obtained by heating manganese acetate) (0.1 per cent was used as additions of 0.01 per cent of the latter oxides to the cement did not produce any significant changes in its rate of hydration).

Cement paste was allowed to hydrate in saturated lime water and the decrease in volume of lime water was noted at intervals of 24 h for 28 days. The decrease in volume represents the amount of water absorbed by the paste, and it was taken to be directly proportioned to the non-evaporable water content of the paste at any particular stage of hydration<sup>1</sup>. The experimental method was the same as that used by Fulton<sup>1</sup>, except that an ordinary glass tube was used instead of a burette and 'Mobil' oil was used as the indicator. Change in volume was calculated from the change in level of oil in the glass tube and from the known average diameter of the tube. Change in volume due to any interaction between oil and lime water was corrected for, at any stage of hydration, by noting the volume changes in a blank with only lime water and oil, under identical setting. All the experiments were simultaneously conducted in a constant temperature room ( $\sim 78^\circ \text{F}$ ).

Results are shown in Fig. 4. The decrease in volume per g of cement at any stage of hydration has been taken proportional to the non-evaporable water content of the hydrated cement at the corresponding stage of hydration. The decrease in volume has been plotted against

Fig. 2. Water absorbed ( $W_a$ )  $\sim \log t$  ( $t$  in sec) for period 4-31 h

Fig. 3. Non-evaporable water content ( $W_n$ )  $\sim \log t$  ( $t$  in sec) for period 1-7 days

Fig. 4. Change in volume,  $\Delta V$ , during setting of cement  $\sim \log t$  ( $t$  in sec); period 1-28 days. Curve (1) is for neat cement; curves 2, 3, 4, 5, 6, 7, 8 are for cement mixed with  $\text{Cu}_2\text{O}$ ,  $\text{ZnO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{MnO}_2$  (7),  $\text{NiO}$ ,  $\text{Cr}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  respectively

$\log t$  (time in sec) (Fig. 4). A linear relationship is obtained. (Other relations, such as inverse logarithmic or inverse mass, do not hold good.) There is a sharp increase in the rate of hydration of neat cement and cement mixed with cuprous oxide, zinc oxide and alumina on the fourth day of hydration. When nickel oxide and oxide of manganese are added to cement the change in the rate of hydration is delayed to the sixth day. With additions of oxide of chromium and iron the hydration rates, which are lowest, remain uniform.

It is seen that during the period 1-28 days, compared with 'pure' Portland cement the non-evaporable water content of cement mixed with cuprous oxide, zinc oxide and alumina is higher at any stage of hydration of Portland cement. That is, the rate of hydration of Portland cement is enhanced by admixtures of these three oxides in traces, but the reverse occurs, during the same period, on addition of chromic sesquioxide, ferric oxide, nickel oxide and oxide of manganese in similar small quantities. Thus the oxides of copper ( $\text{Cu}_2\text{O}$ ), zinc and aluminium act as accelerators and the oxides of chromium ( $\text{Cr}_2\text{O}_3$ ), iron ( $\text{Fe}_2\text{O}_3$ ), nickel and manganese act as retarders—when present in traces. Thus it might be possible to obtain adequate retardation in the hydration of Portland cement clinker by adding traces of these oxides in quantities relatively smaller than gypsum. This may afford a means of eliminating the use of gypsum in Portland cement.

We thus determined that: (1) The rate of hydration follows a direct logarithmic law (we are neglecting the other laws which might be operating during the first few hours of hydration). (2) Sudden changes in the rate of hydration occur at different periods during hydration. (3) The change in hydration rate which occurs at the fourth day may be delayed or eliminated by the additions of oxides containing cations of valency higher than that of silicon. (4) The rate of hydration of cement is enhanced by addition of traces of oxides to cement with cations of valency lower than that of silicon, while the reverse occurs when oxides having cations of valency higher than that of silicon are added (the choice of silicon as the standard is arbitrary at this stage of our discussion).

Logarithmic relationships have also been observed to hold good (among others) in oxidation of metals. These relationships have been deduced by Mott<sup>2</sup>, Cabrera and Mott<sup>3</sup>, Uhlig<sup>4</sup> and Evans<sup>5</sup>. It will be seen that, of these, the basic considerations of Uhlig (leading to a direct logarithmic law) are applicable to hydration of cements. According to Uhlig the rate of oxidation is controlled by

the rate of flow of electrons from metal to oxide—which in its turn is controlled by the work function of metals. It was shown earlier that the hydration of Portland cement clinker takes place by the transfer of electrons from the clinker minerals\*, and that the rate of hydration is controlled by the position of Fermi-level in these minerals and consequently by the thermionic work function (preceding article). It may be that because of the same basic mechanism operating in oxidation of metals and hydration of Portland cement both the processes obey the same rate laws.

Apart from these, it appears that Uhlig's approach to the problem of oxidation of metals is also capable of explaining another unusual finding concerning the hydration of Portland cement. Portland cement is a mixture of minerals. When it reacts with water it would be expected that its constituent minerals would react with water at their individual reaction rates—which vary from mineral to mineral. This, however, does not happen. These constituent minerals, when made into a mixture to form Portland cement, react with water at equal fractional rates (Copeland and Bragg†). This aspect will not be discussed here.

The effects on the rate of oxidation of metals of adding traces of oxides as impurities are as follows: when the oxide scale is an 'n' type semiconducting oxide, minor additions of the cations of valency lower than that of the metal (being oxidized) to the oxide scale raises the oxidation rate, while the reverse occurs when cations of higher valency are added. In 'p' type semiconducting oxides the situation is opposite. In both these cases diffusion of (metal) cation through the oxide layer controls the rate of oxidation. Diffusion is primarily controlled by the defect structure of the oxide.

Correspondingly, in hydration of cements it is known that the hydrated products have defect structures; the exact nature of the defects is, however, uncertain. Moreover, the nature of the diffusing ion in hydrated products and the nature of semiconduction (if any) in them are also unknown. However, there is some indication that the hydrated products may be 'p' type semiconductors (preceding communication). On this basis, hydration ought to take place by anion (OH) diffusion through the hydrated layers.

Acceleration and retardation of the rate of hydration will now be considered. Calcium ions are produced during hydration of calcium silicates. These ions may be absorbed by the clinker minerals or may remain in the body of the hydrated product. In either case, the reaction rate should be enhanced as the adsorption of calcium ions by clinker crystals may raise the Fermi-level of the crystals concerned; this may enhance the reaction rate as

explained elsewhere\* and also for the reason that the valency of calcium is less than that of silicon. The same may hold good for the hydration of tricalcium aluminate where alumina is liberated during hydration. Thus the process of hydration itself may provide for its own enhancement. It may be that the rate constant is controlled by the concentration of the ions liberated during hydration and may have different values for different ranges of concentration of ions.

The amount of hydration in a given time will also depend on the availability of hydroxyl ions which may diffuse through the hydrated layers. These hydroxyl ions would be provided by the water. If the water structure were disturbed, say, by the addition of chlorine ions (from calcium chloride, which is added to cement to accelerate hydration) a greater number of hydroxyl groups would be available for diffusion through the layers. Hence the hydration rate of Portland cement should increase both for calcium and chlorine ions when calcium chloride is added to it. Again the hydration rate is retarded on addition of gypsum to Portland cement clinker. Stabilisation of water structure by the (SO<sub>4</sub>)—tetrahedron fitting into the 'vacancies' in water structure (and thus stabilizing it) may be responsible for fewer hydroxyl ions being available for diffusion through the hydrated layer—and thus leading to a retardation of the hydration process. Thus the extent to which the water structure is stable may be a contributory factor in controlling the rate of hydration of cement. This, however, is to be considered as supplementary to, rather than replacement of, the chemical reasons behind the process of acceleration or retardation of the hydration of Portland cement.

Ions liberated during the hydration of cement should by themselves enhance the rate of hydration. The state of stability of the water lattice may also be a factor in controlling the rate of hydration of Portland cement. The greater the instability, the higher should be the rate of hydration.

## NITROUS OXIDE – ACETYLENE FLAME IN ATOMIC ABSORPTION SPECTROSCOPY

By J. B. WILLIS

Division of Chemical Physics, C.S.I.R.O. Chemical Research Laboratories, Melbourne, Australia

SINCE its introduction some ten years ago the technique of atomic absorption spectroscopy<sup>1</sup> has become a valuable method for the determination of trace concentrations of a wide range of metals in solution, and some 35 metals can be satisfactorily converted to the atomic form by spraying solutions of their salts into a low-temperature, pre-mixed flame such as air-coal gas, air-propane, or air-acetylene.

Metals such as the alkaline earths, chromium, molybdenum, and tin are only partially atomized, however, and chemical interferences tend to occur, while a number of metals such as aluminium, beryllium, silicon, titanium,

tungsten, and vanadium are not appreciably atomized at all in such flames.

The difficulty of completely atomizing the metal to be determined has long been recognized as the principal limitation of the atomic absorption technique in chemical analysis, and this article describes the use of a new type of flame which enables effective atomization of a wide range of metals and overcomes many of the chemical interferences found with conventional flames.

Some success in the atomization of the group of metals already mentioned (aluminium, beryllium, silicon, titanium, tungsten and vanadium) has been achieved by direct

injection of their solutions, usually in organic solvents, into turbulent oxy-acetylene flames<sup>2-4</sup>. Such flames, however, as well as being unpleasantly noisy, are of limited value for absorption measurements as they normally provide only a short light-path.

Amos and Thomas have successfully atomized aluminium<sup>5</sup> and other metals<sup>6</sup> by spraying solutions of their salts into a pre-mixed flame of acetylene and enriched air (50 per cent oxygen), but the high flame speed of this mixture severely limits the size and shape of the orifice at which it can be burned and there is a danger of flash-back if the flow of acetylene is reduced too far while adjusting or extinguishing the flame. The need for supplies of the special oxygen-nitrogen mixture may also prove a drawback.

Clearly it would be desirable to have flames giving the same temperature as that of enriched air-acetylene but with lower burning velocity, and the flames of acetylene burning in oxides of nitrogen suggest themselves. Table 1 shows the characteristics of such flames, together with those of the conventional flames normally used in atomic absorption work.

At the third Australian Spectroscopy Conference (Sydney, 1961)<sup>7</sup>, Mr. J. E. Allan reported that he had experimented with the nitrous oxide-acetylene flame, but these experiments, which were made with a burner having a 4.75 in.  $\times$  0.010 in. slot, were abandoned because of the poor sensitivities obtained<sup>1</sup>.

Since supplies of nitric oxide and nitrogen dioxide are not readily available I have confined my attention so far to nitrous oxide, which is widely distributed in liquid form for anaesthetic purposes. I have found that nitrous oxide-acetylene mixtures can be safely burned at a slot as large as 4 in.  $\times$  0.015 in. in a burner made of  $\frac{1}{8}$ -in. thick stainless steel, and that either gas may be turned off first without danger of flash-back. Water cooling is not necessary, and the burner may be fitted directly to the spray-chamber of an ordinary atomic absorption instrument.

Using a Techtron AA-3 single-beam spectrophotometer and replacing the normal tubular burner with one based on the design of Amos and Thomas<sup>5</sup> and having a 2 in.  $\times$  0.018 in. slot in a  $\frac{1}{8}$ -in. stainless-steel block I have obtained the sensitivities shown in Table 2, which are very similar

Table 1. CHARACTERISTICS OF FLAMES SUITABLE FOR ATOMIC ABSORPTION SPECTROSCOPY

Gas mixture	Maximum flame speed (cm sec <sup>-1</sup> )	Maximum temperature (°C)
Air-propane	82	1,925
Air-acetylene <sup>8</sup>	160	2,800

to those obtained<sup>1,6</sup> with the enriched air-acetylene flame. Sensitivities obtained with a burner having a 4 in.  $\times$  0.015 in. slot are usually much poorer.

Metals such as the alkaline earths, chromium, molybdenum, and tin show enhanced sensitivities with respect to those found in the air-acetylene flame. A particularly pleasing feature of the new flame is the disappearance of chemical interferences: calcium, for example, is not influenced by the presence of 100 times its concentration of phosphorus, nor is magnesium by 1,000 times its concentration of aluminium.

I thank Mr. M. D. Amos for discussion of his results before publication and for the loan of an experimental burner, and Atomic Spectral Lamps Pty., Ltd., for the loan of hollow-cathode tubes.

## OXYGEN ISOTOPIC COMPOSITION OF ORTHOPHOSPHATE FROM SHELLS OF LIVING MARINE ORGANISMS

By DR. A. LONGINELLI

Laboratorio di Geologia Nucleare, Pisa, Italy

UREY *et al.*<sup>1</sup> and Epstein *et al.*<sup>2,3</sup> succeeded in establishing a temperature scale based on the measurement of the isotopic composition of oxygen in the carbonate shells of marine animals and in the environmental waters. In the case of fossils the <sup>18</sup>O/<sup>16</sup>O ratio of the environmental water cannot be measured and palaeotemperatures are generally calculated assuming this ratio as equal to that of modern mean ocean water. This could lead to large errors. The uncertainty could be removed by establishing a second relationship between growth temperature and isotopic abundance of oxygen, for example, in the phosphate of shells. In such a way, measuring the oxygen isotopic composition of carbonate and phosphate from the same shell, and inserting these values into the Epstein equation<sup>3</sup> and in a second one of the same type determined for phosphates, the oxygen-18 content of ancient waters could be obtained.

In 1963 I started a palaeotemperature project with the purpose of establishing a relationship between

the growth temperature and the oxygen isotopic composition of the phosphate of living shells.

The technique used for the purification of the phosphate of shells and the removal of the oxygen by fluorination with BrF<sub>3</sub> is the same as described by Tudge<sup>4</sup>. The conversion of the oxygen to carbon dioxide for spectrometric measurements was made following the technique described by Clayton and Mayeda<sup>5</sup>. The method is summarized as follows.

The phosphatic shells were mechanically cleaned, then washed and air dried, crushed in a steel mortar and ground in an agate mortar. The powder was dissolved slowly with 10 M nitric acid and the organic matter oxidized by addition of 0.3 M KMnO<sub>4</sub> solution. The PO<sub>4</sub><sup>3-</sup> was precipitated twice as (NH<sub>4</sub>)<sub>2</sub> PO<sub>4</sub>·12 MoO<sub>3</sub>·2HNO<sub>3</sub>·H<sub>2</sub>O and then as MgNH<sub>4</sub>PO<sub>4</sub>·6H<sub>2</sub>O. The latter precipitate was dissolved again with 5.4 M nitric acid, then added to bismuth reagent solution (0.2 M Bi(NO<sub>3</sub>)<sub>3</sub>; 2.0 M HNO<sub>3</sub>). The precipitated BiPO<sub>4</sub> was filtered,

washed and dried for 12 h at 90° C then dried again in a vacuum furnace at 130° C for more than 3 h. After that the sample was ready to be introduced into the fluorination tube. To obtain a constant temperature in the vacuum furnace this was heated by vapours of boiling xylene. Xylene was frequently removed to avoid a lowering in the boiling-point (144.4° C), due to possible alteration. The details of the chemical procedure are described in Tudge's paper and have been followed closely with good results. The fluorination apparatus was made using nickel and fluorothane together with 'Hoke 413 K', monel, vacuum tight valves. In these valves 'Teflon' gaskets were used instead of 'Kel-F' gaskets. All metal connexions were silver-soldered. The fluorination reaction was made with samples of 20-30 mg and quantities of BrF<sub>3</sub> between 5 and 10 times the stoichiometric requirements. The reaction tube was pre-fluorinated before each measurement, evacuated for about 1 h, then high-purity dry nitrogen, which was dried further by passing it through a 5-m 'Pyrex'-tube trap at liquid nitrogen temperature, was admitted at a pressure of about 820 mm. After the introduction of the BiPO<sub>4</sub> sample, the reactor was evacuated for 4 or 5 h, then the BrF<sub>3</sub> was introduced, and the reactor was heated at about 100° C for 30 min, although the reaction seemed complete within a few minutes. The oxygen was then held for 3-4 min in each trap of the line at liquid nitrogen temperature, to separate the oxygen from volatile impurities; it was then 'toeplered' into a calibrated volume to calculate the yield of the reaction. The oxygen was then circulated by means of a Toepler pump over a hollow cylinder of carbon made from a spectrographic electrode, heated inductively at about 800°-850° C<sup>4</sup>, while contemporaneously the carbon dioxide was frozen out in a liquid nitrogen cooled trap. To catalyse the conversion to carbon dioxide of the carbon monoxide eventually formed, platinum wire was wound round the carbon cylinder.

Oxygen was run in three different portions of about 98, 3.8 and 0.2 per cent. Each portion was run to completion, then the successive portion was added. In this way<sup>4</sup> one can avoid large fractionation effects due to incomplete conversion to carbon dioxide of the carbon monoxide eventually formed. The reaction yield was then measured with a manometer and the <sup>18</sup>O/<sup>16</sup>O ratio of the sample was measured by means of an 'Atlas M88' double collector mass spectrometer. The results are given in the  $\delta$  terminology, as deviations in per mil of the <sup>18</sup>O/<sup>16</sup>O ratio from that in standard:

$$\delta = 1,000 \left( \frac{{}^{18}\text{O}/{}^{16}\text{O} \text{ sample} - {}^{18}\text{O}/{}^{16}\text{O} \text{ standard}}{{}^{18}\text{O}/{}^{16}\text{O} \text{ standard}} \right)$$

In order to avoid isotopic contamination all the conditions outlined by Tudge were fulfilled.

To check the reproducibility of the conversion of oxygen to carbon dioxide, and of the whole procedure, several measurements were made. Thirteen samples of purified tank oxygen were converted to carbon dioxide during different days and the samples of carbon dioxide analysed with two different 'Atlas M88' mass spectrometers. The working standard was carbon dioxide from a very pure white Carrara marble the <sup>18</sup>O/<sup>16</sup>O ratio of which is -1.80 parts per thousand compared with PDB-1 Chicago standard. This working standard was preferred for phosphate measurements because of its reproducibility, which has been well tested for many years. (A limestone, the  $\delta$  value of which is about -18.0 against PDB-1, is being tested for reproducibility for use as a working standard for further phosphate measurements.) The results obtained are listed in Table 1. The standard deviation calculated is  $\pm 0.12$  parts per thousand.

The reproducibility of the complete procedure was checked using four different samples obtained by mixing chemically pure reagent Ca<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub> with a powdered calcium carbonate shell. Each sample was purified using the standard chemical procedure and then divided into

\* As in Table 1.

two or three portions which were fluorinated separately. A total of ten measurements was made using two different mass spectrometers. The results are given in Table 2. The standard deviation is  $\pm 0.28$  parts per thousand. Considering the large difference between the standard and the samples and the use of different mass spectrometers this deviation is to be considered as an upper limit.

The choice of the living species which could be used was made at first on the basis of the results reported in Vinogradov's review<sup>7</sup> on the chemical composition of marine organisms. The purpose was the selection of the largest number of marine organisms with measurable amounts of phosphate in their shells or skeletons for utilization for an isotopic phosphate-water temperature scale, and for measurements on fossils. Different species and different specimens of the same species were analysed for their phosphate content. At present about one hundred species have been examined. These results will be published later. Owing to the small number of species containing appreciable amounts of phosphate and to the difficulty of obtaining samples, a first group of ten species was selected, containing both carbonate and phosphate. The oxygen isotopic composition of phosphate was measured as already described and that of carbonate was measured using the standard technique<sup>8</sup>. The main purpose of these first measurements was to obtain information on the range of the oxygen isotopic composition of phosphate in marine animals and on the possibility of a relationship with the growth temperature.

Because of the small content of phosphate, generally several specimens from the same fauna were processed together. The species measured, their location and the results obtained are listed in Table 3. The analytical results are reported against two different standards: carbon dioxide produced from PDB-1 by reaction with 100 per cent phosphoric acid, and standard mean ocean water (SMOW) as defined by Craig<sup>9</sup>. It must be pointed out that in the case of carbonate the difference of the oxygen isotopic composition between the carbon dioxide from the sample and the carbon dioxide from the PDB-1 standard is equal to that between carbonates. It is known that the <sup>18</sup>O/<sup>16</sup>O ratio in the carbon dioxide liberated from a carbonate by reaction with phosphoric acid is higher by about 10 parts per thousand than that in the carbonate itself<sup>8</sup>:

$$\alpha = \frac{({}^{18}\text{O}/{}^{16}\text{O})\text{CO}_2}{({}^{18}\text{O}/{}^{16}\text{O})\text{CaCO}_3} = 1.01$$

In the case of carbonates the chemical preparation of the sample is the same as that of the standard. The same fractionation effects are determined, thus preserving the value of the difference of the oxygen isotopic composition between the carbonates.

This is not the case with phosphates. The phosphate oxygen is extracted quantitatively by a chemical reaction involving no isotopic fractionation, and then converted to carbon dioxide. The difference between the oxygen isotopic composition of this carbon dioxide and of the carbon dioxide liberated from PDB-1 by reaction with phosphoric acid is not equal to that between phosphate and PDB-1 carbonate.

The  $\delta$  values of carbonates and phosphates are given also against SMOW. They were calculated by the equation:

$\delta_{(x-st.2)} = \delta_{(x-st.1)} + \delta_{(st.1-st.2)} + 10^{-3} \delta_{(x-st.1)} \delta_{(st.1-st.2)}$  (1) by which an isotopic analysis of a sample  $x$  reported relative to a standard (st.1) may be converted to a  $\delta$  value relative to another standard (st.2),  $\delta_{(st.1-st.2)}$  being the difference of isotopic composition between standard 1 and standard 2 expressed in per mil.

From the equation given by Craig<sup>19</sup> the following value is assumed:

$$\delta_{\text{PDB-SMOW}} = +30.6$$

Taking into account the fractionation in the extraction of the carbon dioxide by reaction with phosphoric acid one gets:

$$\delta_{\text{CO}_2, \text{PDB-SMOW}} = +40.9$$

From these values and from equation (1) the isotopic compositions relative to SMOW are easily obtained.

The results are shown graphically in Fig. 1 and are corrected for the effect of the isotopic composition of the environmental water. The values used for this correction are +1.0 parts per thousand for Mediterranean species and -1.0 parts per thousand for species from Newfoundland Grand Bank. These values are only approximate, and have been deduced from some measurements of the Tyrrhenian surface sea-water in the collection area (Table 4) and on three measurements made on the Grand Bank bottom water. From these three measurements, and taking into consideration the variability during the year of the influx of water from the Labrador current, the average value of -1 parts per thousand relative to SMOW seems to be a reasonable one. The oxygen isotopic composition of phosphate is given against the growth temperature, as calculated from Epstein equation. The calculated temperatures are very close to the values which can be theoretically predicted on the basis of biological and physical considerations. The only exception is that of

crabs *Brighia spinifrons* and *Portunus* sp., which are supposed to form their shell along the coast of Tuscany at a temperature of about  $19^\circ \pm 4^\circ \text{C}$ . In this case a biological fractionation effect is probable either in carbonates or in phosphates. A sting ray from the Pacific Ocean and a *Squilla mantis* shell from the Tyrrhenian Sea were also measured ( $\delta$  values versus carbon dioxide from PDB-1):

Sting ray:  $\delta^{18}\text{O}(\text{PO}_4^-)$ -21.90;  $\delta^{18}\text{O}(\text{CO}_3^{2-})$ -6.20.

*Squilla mantis*:  $\delta^{18}\text{O}(\text{PO}_4^-)$ -17.50;  $\delta^{18}\text{O}(\text{CO}_3^{2-})$ -65.5 but the large fractionation effects shown by their calcium carbonate do not permit one to draw conclusions on the validity of the results.

Unfortunately these results cannot be compared with those of Tudge, which were given against a working standard of unknown oxygen isotopic composition.

The following conclusions can be drawn from this first group of measurements.

(a) The range of the oxygen isotopic composition of the phosphate precipitated by *Palaemonetes* and other marine animals is rather far from that of the calcium carbonate. Relating both measurements to the PDB-1 Chicago standard, and bearing in mind the fractionation effect determined by the chemical reaction of  $\text{CaCO}_3$  with phosphoric acid, the difference between the  $^{18}\text{O}/^{16}\text{O}$  ratios is about 12 parts per thousand.

Fig. 1. Oxygen isotopic composition of phosphate from shells of living marine organisms against growth temperature. The  $\delta$ 's are corrected for the effect of the isotopic composition of the environmental water.

Table 4. OXYGEN ISOTOPIC COMPOSITION OF SEA-WATER FROM THE COLLECTION AREAS OF PHOSPHATIC SAMPLES

Samples and their location	Average $\delta^{18}\text{O}$ (SMOW)
8 surface samples 5 miles off La Spezia (August)	+1.10
6 coastal samples near Livorno (September–October)	+0.85
2 surface samples 3 miles off Calvi (Como) (December)	+1.15
2 surface samples Gulf of Genoa (July)	+1.05
2 bottom samples (80 m.) 44° 11' N (end of May) 45° 25' W	-1.20
1 bottom sample (80 m.) 45° 02' N 51° 35' W (July 1)	-1.45

(b) There exists a relationship between temperature and oxygen isotopic composition of phosphate. From the fact that there is a good agreement in the results obtained from different marine animals (Lamelli-branchiata, Cirripedia, Cephalopoda and Brachiopoda) one can assume that the precipitation of phosphate takes place in these cases under isotopic equilibrium conditions. If this is so, crabs seem to precipitate the calcium phosphate of their shell under non-equilibrium conditions. This probably happens also to other crustaceans. To check if there is a constancy of the biological fractionation effect, some crabs are being grown under controlled temperature conditions.

(c) Owing to the small number of samples and to the fact that specimens were not grown under controlled temperature conditions an equation is not given. However, the slope of a straight line calculated by the least-squares method is about -4.1. This value of the slope is very near to that calculated for carbonates (-4.3). Because of that it seems rather difficult, at least on the

basis of these first results, to state a phosphate-carbonate temperature scale. Phosphatic brachiopods will be grown under controlled-temperature conditions. It is possible to obtain from them measurable phosphate samples, a definite equation will be given from which it will be possible to prove the foregoing assumption or to check the possibility of deducing correct values of the oxygen isotopic composition of the sea-water from the carbonate and the phosphate equations.

(d) From the results obtained the fractionation factors can be calculated as follows:  $t = 25^\circ \text{C}$ ,  $\alpha = 1.0156$ ,  $t = 0^\circ \text{C}$ ,  $\alpha = 1.0218$ . These  $\alpha$  values are bigger than those calculated theoretically by Urey *et al.*<sup>1</sup>, which were:  $t = 25^\circ \text{C}$ ,  $\alpha = 1.0087$ ;  $t = 0^\circ \text{C}$ ,  $\alpha = 1.0104$ .

I thank Prof. E. Tongiorgi, Dr. H. Craig and Dr. R. Gonfiantini for their advice. I also thank Mr. S. Nuti for his assistance and the officers and crew of the M.S. *Genepesca I* for their help during the collection of Atlantic specimens.

## CRYSTAL-GROWTH POISONING OF *n*-PARAFFIN WAX BY POLYMERIC ADDITIVES AND ITS RELEVANCE TO POLYMER CRYSTALLIZATION MECHANISMS

By G. A. HOLDER and Dr. J. WINKLER

Imperial Oil Enterprises, Ltd., Sarnia, Ontario

IN recent years much attention has been directed to crystal growth mechanisms in polymers. The growth of polyethylene crystals from solution has been studied particularly intensively. The earlier work showed that long-chain *n*-paraffins and polyethylene crystallized from solution as lozenge-shaped plates<sup>1</sup>. In addition it has been shown that a dendritic type of growth is also common in polyethylene, and that by varying the conditions of crystallization a gradual transition between regular lozenges and dendrites could be obtained<sup>1</sup>.

We wish to report that during studies of *n*-paraffin wax crystallization from middle distillate fuel oils it has been found that if several hundred parts per million of certain polymers are present in the oils, the crystal growth habit of the wax is changed from lozenge-shaped plates to dendrites and other forms. The findings, although of considerable general interest in their own right as examples of crystal-growth poisoning, are of particular value because of the similarities between the crystal habits of the wax and those reported in the literature for polyethylenes and other polymers<sup>2</sup>. Since the dendritic growth which we observed in *n*-paraffinic wax is caused by the presence of a polymer which interferes with the normal course of crystallization one can speculate, for example, that the dendrites reported for polyethylene may have been produced as a result of crystal modifiers which occur naturally in the polyethylenes.

The photographs of the wax crystals were taken with a Leica 35-mm camera fitted to a Leitz 'Laborlux' microscope using phase contrast transmitted light illumination.

Early in the investigations it was found that the cooling rate and the environment could have a marked influence on the size and shape of the wax crystals. Accordingly, all the photomicrographs presented in the paper were obtained by cooling the solutions in bulk (that is, minimum sample size 25 g) in a cold room using carefully controlled cooling rates in the range 0.2–2° F/h. When the wax crystals appeared, a few drops of each solution were transferred from the bulk containers on to a microscope slide, using a spatula, and then photographed. Where not stated otherwise, the polymeric additive used in the work described here was an ester-type copolymer which is available commercially as a 50 per cent solution in kerosene under the trade name 'Paradyne 20' (ref. 3). However, it has been found that similar photographs can be obtained whether the ester-type copolymer or a purely hydrocarbon-type is used as the additive<sup>4</sup>.

In the absence of any copolymer, the wax precipitated as overlapping and intergrowing lozenge-shaped crystals. In the presence of dissolved copolymer a considerable variety of crystal shapes and sizes was observed depending on the polymer concentration and the growth conditions.

The effect of 500 parts per million of dissolved copolymer on the wax crystallization is illustrated in Figs. 1, 2 and 3.

Fig. 1 shows a typical wax crystal produced on cooling a light catalytically cracked oil. The photograph shows an excellent example of dendritic growth and is very similar to many photographs of polymer crystals published in the literature<sup>3</sup>. Detailed investigations of the different types of dendrites which can be formed by polyethylene have been carried out by Wunderlich<sup>4</sup>. Corresponding types have also been observed with wax by ourselves. Fig. 2, for example, shows a twin dendrite which was obtained by cooling the same oil referred to in Fig. 1 at 2° F/h, instead of 1° F/h. In contrast, Fig. 3 shows a dendritic type unlike any yet published for polyethylenes. However, it should be mentioned that it is very doubtful whether any correlation between the type of dendrite and the crystallization conditions can be established since a number of structures can usually

Fig. 1. *n*-Paraffin dendrite produced by cooling (at 1° F/h) light catalytically cracked oil containing 500 p.p.m. copolymer

Fig. 4. Typical composition of the dendritic *n*-paraffin wax crystals

Fig. 5. Block-like and pyramidal *n*-paraffin crystals produced by cooling (at 1° F/h) a 50/50 blend of virgin and cracked oils containing 1,000 p.p.m. hydrocarbon copolymer

be distinguished in any given solution. Dendrites have been found in a wide variety of oils which have been treated with the additive. A gas chromatographic analysis on dendritic wax filtered from a typical oil is presented in Fig. 4. The wax consisted of C<sub>17</sub>-C<sub>24</sub> *n*-paraffins in solid solution accompanied by trace amounts of isoparaffins. The polymeric additive composition is important, but not critical, provided certain structural requirements are met.

Very often block-like crystals are produced at relatively high concentrations of copolymer. This effect is illustrated by the photograph shown in Fig. 5. These block-like crystals appear to be formed from would-be pyramidal crystals which have not completed their growth independently.

So far, true dendritic crystals have been observed only when mixtures of *n*-paraffins are crystallized in the presence of copolymer. Attempts to obtain true dendrites by: (a) crystallizing pure single *n*-paraffins from solution in the presence of copolymer, and (b) by crystallizing selected mixtures of *n*-paraffins in the absence of copolymer have been unsuccessful.

The mechanism by which dendritic growth occurs has been discussed in detail by Saratovkin<sup>5</sup> with reference to alloys and inorganic crystals. Essentially the same basic mechanism can be used to explain the way in which the

copolymers change the habits of the wax crystals<sup>4</sup>. We therefore propose that the dendritic wax crystals are obtained because the copolymers modify the crystal habit of the *n*-paraffin wax by selectively poisoning the growth of the wax crystals in the 011 (or *XY*) crystallographic plane.

The copolymer molecules are made up of runs of methylene groups which are broken periodically by branching. The poisoning action probably occurs because the copolymer molecules are sufficiently similar to the *n*-paraffins to incorporate themselves at the wax crystal growth step (perhaps by chain folding) and yet sufficiently dissimilar (by virtue of their branches) to obstruct the further addition of *n*-paraffin molecules to the crystal. When crystal growth is retarded in the 001 plane the crystal will grow relatively faster along its *Z* axis. Consequently 'thicker', that is more isometric, wax crystals are produced when copolymer is present. At high polymer concentrations, growth in the 001 plane is evidently restricted to such an extent that even dendrites cannot form; instead much of the crystal growth takes place along the *Z* axis and block-like or pyramidal crystals result, as is illustrated in Fig. 5.

The remarkable changes in the crystal growth habits of *n*-paraffin wax produced by low concentrations of polymers

are probably idealized examples of effects which are operating in many other systems. In particular, we think that similar mechanisms may well apply to polymer crystallizations themselves, and also to enzyme and protein crystallizations reported in the literature, for example, refs. 7 and 8. In these systems the crystals consist of mixtures of complex molecules. The crystal poisons would be present either as impurities or, more likely, occur naturally as components of the polymers themselves. In either event, the results clearly emphasize the desirability that morphological investigations of the crystallization of complex molecules should preferably be carried out under carefully controlled conditions and using only material which has been carefully purified.

A more detailed report on the mechanism of the poisoning will be made in a later publication<sup>5</sup>.

## DISCONTINUITIES IN LIQUID FLUIDIZED BEDS

By DR. N. J. HASSETT

Loughborough College of Technology, Loughborough

IN an earlier communication<sup>1</sup> attention was directed to hitherto unsuspected discontinuities in liquid fluidized beds. Attention is now directed to a parallel existence of discontinuities in sedimentation. When aqueous dispersions of a variety of materials are settled, small mounds and craters are frequently observed on the surface of the

final sediment. This has been noticed in the case of natural products such as clays as well as chemical precipitates, and constitutes evidence of some sort of channeling effect in the sediment.

It is known that fine particles often settle as flocs, an individual floc comprising an aggregate of particles

Fig. 1

Fig. 2

Fig. 3

Fig. 4

embracing a core of liquid, with the result that the sediment initially had a low solids content. A natural inference is that a subsequent slow collapsing of the flocs releases liquid which, in percolating upwards through the sediment, creates preferential channels of flow, with possible formation of mounds by either of two mechanisms. Closer observation, however, has shown that these channels are initiated at a relatively early stage of settling, and in the disperse phase.

Figs. 1-4 show stages in the sedimentation of an aqueous dispersion of a precipitated chalk, initially at uniform

Fig. 5

Fig. 6

Fig. 7

concentration 0.02 v/v, in a glass measuring cylinder of 4 cm internal diameter. Within 3 min of commencement of settling, in which time the upper level had fallen less than 5 mm of its original height of 230 mm, the suspension showed signs of curdling and slight scores could be seen at the cylinder wall. As time progressed the scores developed into sensibly vertical or upwards-inclined channels of some 1-2 mm wide, wherein liquid streamed upwards carrying fine particles seemingly as individuals rather than as flocs, at a linear velocity of some 5 mm/sec. In reaching the surface they formed miniature volcanoes as seen clearly sectioned at the wall in Fig. 4.

That this is not merely a wall effect is shown by Figs. 5 and 6, taken at the surface of another sediment, where the eruptions chanced to be located randomly away from the wall. Such eruptions are often apparent at the surface about 10-15 min after the beginning of settling, in the case of suspensions at volume dilutions of between 15 and 50 : 1. The suspensions are quite fluid at the time of formation and for a considerable period thereafter, as demonstrated by the response to any slight movement of the cylinder. Despite the fluidity of the suspension, the channels are most persistent in their location, although random making and breaking can be observed as might be expected. The random nature of channel formation indeed could be largely responsible not only for the anomalous nature of many batch-settling curves, but also for the variations and differences noted in repeat batch-settling experiments.

It is interesting to observe that where suspensions of initial concentration greater than 0.06 did not give visual evidence of curdling or channelling at the wall, small mounds were nevertheless formed more centrally at the surface. It could be inferred as a general conclusion that channels initiate in accord with flow patterns in a suspension, which are set up by the prior shaking to obtain a uniform suspension, and persist for some time after commencement of settling.

Fig. 7 shows part of the surface of a sediment in a tank of some 40 cm  $\times$  60 cm cross-section. Here the eruptions have spread over wider areas, the larger spreads having a diameter of the order of 10 cm, and now another phenomenon is observed. This is a lateral shrinking of the sediment to form a series of vertical fissures. The horizontal scores which can be seen extending mainly over the non-fissured area are also of interest. That they are not extraneous seems evident since they do not extend across the eruption-spread areas.

The existence of channels explains certain anomalous measurements made in continuous thickening experiments in a tank of some 100 cm diameter and 200 cm deep, where hydrostatic head measurements at a series of depth intervals indicating quantity of suspended matter are

made to an accuracy of 0.01 mm water. Random fluctuations with an amplitude of up to 0.60 mm can now be explained in terms of such channelling.

Finally, the similarity of Fig. 5 to the appearance of a gentle bubbling gas fluidized bed is noted, and the possibility that dispersions of non-flocculated particles should settle with formation of parvoids cannot be excluded.

I thank Mr. J. Gascoine, of the Loughborough College Photo-printing Unit, for the photography, and the Department of Scientific and Industrial Research for a grant covering a wider investigation, enabling the engagement of junior research assistants. One of these, R. Buxton, assisted in the setting up of the experiments.

## HYBRIDIZATION OF LACTIC DEHYDROGENASE *in vivo* AND *in vitro*

By DR. STANLEY N. SALTHER, DR. OSCAR P. CHILSON and PROF. NATHAN O. KAPLAN

Graduate Department of Biochemistry, Brandeis University, Waltham, Massachusetts

ON the basis of a variety of observations it is generally accepted that lactic dehydrogenase (LDH) is composed of four sub-units, and that two basic types of sub-unit are present in tissues of most species<sup>1,2</sup>. Muscle or *M* type is the principal form in skeletal muscle, and heart or *H* type predominates in heart<sup>3,4</sup>. The various forms of LDH are represented schematically in Fig. 1. In contrast to mammals and birds, tissue extracts of a number of vertebrates do not show the 'normal' five bands of LDH activity on starch-gels. Several species have more than five bands in complex patterns which may be due to 2 *M* or 2 *H* types<sup>5</sup>. In several species as few as two electrophoretic bands are found. Implicit in the interpretation of electrophoretic patterns is the idea that, within a given cell type, random combination of LDH sub-units occurs, and that all possible combinations are stable under the experimental conditions; otherwise interpretation is complicated, if not impossible.

Fig. 1. Nature of the multiple molecular forms of lactic dehydrogenase

The development of methods that permit the formation of inter- as well as intra-specific hybrids<sup>6,7</sup> makes possible the investigation of fundamental questions concerning the degree of structural similarity among various LDH's and the interpretation of electrophoretic patterns.

The experiments of Singer and Itano<sup>8</sup> and subsequent investigations have shown that a very wide variety of haemoglobins can hybridize *in vitro* by treatment at low pH (refs. 9 and 10). It has also been shown that the structural features required for the formation of functional haemoglobin tetramers have been largely conserved during evolution<sup>11</sup>, even though the amino-acid sequences, oxygen-binding capacities, Bohr effects, and immunological properties of these proteins are different<sup>12-14</sup>.

More recently Huehns *et al.*<sup>15</sup> have observed hybridization of haemoglobins *in vitro* at neutral pH at 38° C. Their technique permits measurement of relative rates of hybridization, and in the course of their investigations they observed large differences in rates of interaction

between certain types of sub-units; it was suggested that differences in rates of interaction between haemoglobin sub-units also occur *in vivo*<sup>16</sup>.

In some respects our studies on LDH parallel investigations on haemoglobin. Both proteins are tetramers and have four 'active sites', and X-ray crystallographic studies have shown that at least one LDH has properties of symmetry comparable with those of haemoglobin<sup>17</sup>. Within a given species the *H* and *M* sub-units are catalytically and immunologically distinct and have different amino-acid sequences, but form functional hybrids. Therefore it was of interest to determine whether haemoglobin was unique in its ability to form functional interspecies hybrids, and to compare rates of hybrid formation between different types of LDH sub-units.

### Hybridization *in vitro*

Most of our experiments have been carried out with highly purified crystalline enzymes, but since hybridization also occurs in crude extracts, the degree of purity of the enzymes apparently is not critical. Purified enzymes or crude extracts were dialysed overnight against 1.0 M sodium chloride + 0.1 M sodium phosphate (pH 7.0), mixed, frozen in a dry-ice-methanol bath, and allowed to thaw at room temperature. Samples were then dialysed for 3-12 h against 0.1 M sodium phosphate (pH 7.0) to reduce the salt concentration, and subjected to starch-gel electrophoresis<sup>4</sup>. Table 1 summarizes the combinations which we have subjected to hybridizing conditions, and indicates whether or not hybrids were formed, and whether binomial electrophoretic patterns were produced.

Most of the enzyme combinations hybridized readily, showing that those structural features which are required for tetramer formation have been largely conserved during evolution. These results are in agreement with the preliminary observations of Markert<sup>17</sup>.

A number of interesting exceptions with respect to hybridization were observed. The *L* lactic acid-specific LDH from *Lactobacillus orabimosis* did not hybridize with dogfish *M* LDH, and when combinations of dogfish *M* LDH were frozen and thawed with lobster muscle LDH a faint, smeared band, staining for both enzyme activity and protein, and with electrophoretic mobility intermediate between the two pure types, was observed. Apparently hybrids were formed but were somewhat unstable.

Table 1. INTERSPECIFIC HYBRIDIZATION OF LACTIC DEHYDROGENASES

Bullfrog heart + leopard frog heart	+	-

Dr. A. O. Wilson of this Laboratory observed that tissue extracts from several species did not contain hybrids between *H* type and *M* type LDH's; they included the hagfish (*Myxostoma stouti*), the bullfrog (*Rana catesbeiana*), the congo eel (*Amphiuma tridactyla*), the codfish (*Gadus calarias*) and the haddock (*Melanogrammus aeglefinus*). In these species no tissues were found that showed hybrids, even though the two pure types were present in some. In the bullfrog a single faint band with a mobility approximately equidistant from the *H* and *M* bands was observed. Failure of the *H* and *M* enzymes of these species to hybridize *in vivo* is not neces-

sarily due to synthesis in separate cell types, because when extracts of these species were subjected to hybridizing conditions (by the freeze-thaw technique<sup>6</sup>) hybrids were not formed, and the undefined intermediate band in bullfrog tissue was not intensified (Fig. 2).

Failure to form hybrids *in vivo* under a given set of conditions may be due either to failure to dissociate into sub-units or to much lower rates of combination of sub-units into hybrids, as compared with reformation of the pure types. In previous reports we have presented evidence that, by varying the ionic strength, the nature of the ions, and coenzyme analogue concentrations, different LDH's will show quite different rates at which their sub-units will hybridize<sup>7,10</sup>. In order to test these two alternative hypotheses attempts were made to hybridize the *H* type and *M* type LDH's of the species that failed to hybridize *in vivo* as well as *in vitro*, with *H* type and *M* type enzymes of other species. Although the *M* type enzymes of codfish, haddock, congo eel, and bullfrog do not hybridize *in vivo* or *in vitro* with their corresponding *H* type LDH's, they do hybridize *in vitro* to give binomial patterns of multiple forms with *H* type enzymes from other species. This demonstrates that these *M* type enzymes have structural features sufficiently similar to other LDH's so that functional tetramers can be formed. When similar experiments were done with heart extracts from cod, haddock, bullfrog and congo eel, it was found that the *H* type enzymes differed markedly from their specific *M* types in their ability to hybridize under these conditions with other LDH's. A schematic representation of the kinds of patterns that were observed is shown in Fig. 2.

These results suggest that absence of hybrids *in vivo* is not necessarily owing to involvement of different cell types, and failure to hybridize *in vitro* is not necessarily owing to complete absence of dissociation. It is possible that when mixtures of *H* type and *M* type extracts from cod, haddock, bullfrog and congo eel are frozen and thawed, at least partial dissociation occurs but that the parent types are reformed in preference to hybrids. The results shown with chicken *H*<sub>4</sub> and bullfrog *H*<sub>4</sub> indicate that, although some hybridization occurs, the parent forms are still kinetically favoured. Since roughly one-third of the activity is lost under the freeze-thaw conditions, an alternative hypothesis is that failure to observe hybrids may be due to their instability.

We have found, for example, that the *H* type enzymes of different populations of bullfrogs have different stabilities at low pH. *H* type LDH from Louisiana bullfrogs shows no loss of activity at pH 5.6, whereas the same enzyme from Wisconsin bullfrogs loses half its activity after an hour at this pH. This is reflected in starch-gel, where there is a pH gradient from anodal to cathodal ends, in an absence of the heart band from Wisconsin populations but not from Louisiana populations. Differential heat stabilities result in similar distortions of starch-gel patterns, since there is also an anodal-cathodal temperature gradient along the gels.

#### Hybridization *in vivo*

We have carried out experiments which demonstrated a remarkable effect of environmental conditions on sub-unit association. The *H* type LDH's of the leopard frog, *Rana pipiens*, and of the pickerel frog, *Rana palustris*, do not hybridize *in vitro* with each other or their corresponding muscle types. However, binomial patterns of hybrid *H* types were formed *in vivo* in hybrid tadpoles between these species. Eggs were obtained from female *Rana pipiens* by the pituitary implant method<sup>11</sup>, and fertilized with a sperm suspension from ground testes of male *Rana palustris*. The tadpoles were reared until large enough for the hearts to be conveniently removed. Fig. 3 shows the electrophoretic patterns of the LDH's in crude extracts of hearts both of

Fig. 2. Sketch of starch-gel electrophoretic patterns comparing hybridization between LDH's from heart and muscle of various species

Fig. 3. Pattern of heart LDH of parental and hybrid frog hearts. 1 and 5, *Rana pipiens*; 2, 4 and 6, *Rana pipiens* x *Rana palustris* run at three different concentrations of enzyme activity in order to bring out different characteristics of the pattern; 3 and 7, *Rana palustris*. Electrophoresis was done on starch gel with citrate phosphate buffer at pH 7, 30 h. The gel was made up in half-strength buffer to increase the voltage, thereby increasing the separation of the sub-bands.

the parental species and of the hybrids. It is apparent that the products of the homologous genes of these species can combine to form biologically active hybrid molecules. Our success in hybridizing these two enzymes *in vivo* indicates that there may be *in vitro* conditions under which the various refractory heart LDH's will dissociate and reassociate, forming stable hybrid enzymes. These conditions have not yet been discovered, and the sub-units of this group of *H* type LDH's remain peculiar in this respect. In this case we have clearly shown that failure to produce hybrids *in vitro* is not due to hybrid instability because the *H*-type hybrids of *Rana pipiens* and *Rana palustris* produced *in vivo* are quite stable.

From our work with embryos we have observed that in *Rana pipiens*, *Rana palustris* and *Rana sylvatica*, the ova as they are deposited contain primarily the *H* type LDH, so far as can be determined by starch-gel electrophoresis. There is no observable change in electrophoretic pattern until about the time of hatching (Shumway stage 19), when the *M* band begins to become more intense. At this time also, in the hybrid embryos, the paternal *H* type LDH makes its first appearance on starch-gels, together with the hybrid LDH's composed of both paternal and maternal sub-units (Fig. 4). This figure indicates the presence of two faint intermediate bands between the *M* and *H* types. These bands appear to be similar to the single intermediate band in the bullfrog (Fig. 1). Like that band, they cannot be intensified by freezing and thawing muscle and heart extracts together. For this reason we feel that they may not be hybrids of *H* and *M* sub-units. Hybrids between the *M* sub-units of the two species cannot be seen on gels because they have identical mobilities. We have found that the *M* type LDH's of these two species are identical by every criteria that we have applied. They do not differ immunologically, catalytically, in temperature stability, or in electrophoretic mobility. The *H* LDH's of these two species, however, differ in all these respects.

It is not clear from electrophoresis alone at what point in development the *M* type LDH and paternal *H* LDH are first produced. They may be present at any stage before the one when they are first seen on starch gels, but in such small amounts, or concentrated in so few cells, as compared with the whole embryo, that they are below the limits of resolution of this method. The first appear-

ance of paternal *H* type and the first intensification of the *M* type coincide with the rise in enzyme activity per embryo reported to begin at around the hatching stage by Wallace<sup>10</sup>. We have confirmed Wallace's observation that before this stage there is no change in the level of LDH activity. It is possible that until this stage the enzyme activity in the embryo is caused wholly by the LDH already present in the ovum, and that the embryo does not begin to produce its own LDH until the hatching stage. Since both the initial intensification of the *M* type and the first appearance of the paternal *H* type occurs at the same stage, the structural genes responsible for their production appear to begin functioning at the same time.

On the basis of their tendencies to form hybrids under various conditions, LDH's can be divided into three broad groups. First, there are those that hybridize *in vitro* in an apparently random fashion with no types favoured kinetically. This group includes the majority of the LDH's that have been studied. Secondly, there are those *H* type LDH's (for example, bullfrog *H* type, congo eel *H* type, haddock *H* type) that will not hybridize with certain LDH's but will partially hybridize with others. In these cases dissociation apparently occurs, but the pure types are kinetically favoured. Thirdly, there are those *H* type LDH's (*Rana palustris H* and *Rana pipiens H*) which do not hybridize *in vitro* with any other LDH's under the conditions employed. Since no enzymes have been found that will hybridize with these types *in vitro* we cannot say whether these enzymes do not dissociate under these conditions; but *in vivo* conditions are such that random combination of sub-units does occur. However, the *H* types of *Rana pipiens* and *Rana palustris* do not appear to hybridize with their corresponding muscle types *in vivo*. By way of comparison with other species that have been studied, it does not seem reasonable that this phenomenon should be explained simply on the basis of synthesis in separate cell types. It is possible that the mechanism of synthesis within a given cell type controls which sub-units are put together. There is the alternative possibility that when the two *H* LDH's are synthesized in the same cell there is no preference of one sub-unit for another (Fig. 3), but when *H* and *M* sub-units are synthesized in the same cell the pure types are kinetically favoured.

Thus far the only sources of LDH's that will not form random hybrids *in vitro* with the usual techniques are the hearts of cold-blooded lower vertebrates, these being some frogs and salamanders as well as some teleost fishes. Since the sharks (dogfish) and birds and mammals do show normal hybrids between the heart and muscle sub-units, their absence in the groups indicated appears to have been an independent evolutionary acquisition in each of these three groups. This is further indicated by the fact that

Fig. 4. Starch-gel electrophoretic patterns showing changes during development of hybrid and control embryos. Electrophoresis was done on starch gel with citrate phosphate buffer, at pH 7, 15 h. Under these conditions the hybrid *H* types do not separate, but the single band representing them is intermediate in mobility between the maternal and paternal *H* types.

in species of frogs and salamanders considered to be primitive on gross morphological grounds, the hynobiid salamanders, pipid frogs, and some discoglossid frogs, the usual three hybrids plus the pure *M* and *H* enzymes do occur (Salthe, unpublished). Since the muscle sub-units of all these species will hybridize *in vitro* with other kinds of LDH sub-units, this peculiar evolutionary change appears, from the data so far available, to have occurred in the heart sub-units only.

It would seem from these observations that the structural genes responsible for the production of *H* and *M* type sub-units have been evolving at different rates in some groups of vertebrates, the *H* sub-units undergoing greater modifications in some lower vertebrates than the *M* sub-units.

This work was supported in part by research grants from the U.S. Public Health Service, National Institutes of Health (CA-03611), the National Aeronautics and Space Administration (NSG-375), and the American Cancer Society (P-77F). ## DDT IN HUMAN MILK

By DR. GRIFFITH E. QUINBY\*, JOHN F. ARMSTRONG  
and DR. WILLIAM F. DURHAM

Toxicology Section, Technology Branch, Communicable Disease Center, Public Health Service,  
U.S. Department of Health, Education and Welfare.  
Wenatchee, Washington

IN 1960, Laug *et al.* investigated the DDT excretion-level in human milk in the United States<sup>1</sup>. These workers found DDT in 30 of 32 samples (94 per cent) of milk from women in Washington, D.C., with no recognized exposure to this insecticide other than that of the general population. The average concentration of DDT in these samples was 0.13 p.p.m. with a range of zero to 0.77 p.p.m. In 1962, tests on six individual samples and one pooled sample of human milk in California showed DDT-levels ranging from zero to 0.12 p.p.m. and DDE contents from none to 0.25 p.p.m.<sup>2</sup>. The highest total of DDT and DDE was 0.37 p.p.m. In Hungary, the milk of ten health nursing mothers was found to contain from 0.13–0.26 p.p.m. of DDT in whole milk or 3.3–6.6 p.p.m. in the lipid fraction<sup>3</sup>.

This article reports the excretion of DDT in human milk as measured in individual and pooled samples collected in several cities in the United States during 1960 and 1961. The work is a component part of a more comprehensive study. The complete project involves determination of DDT and DDE storage-levels in body fat and DDA excretion rates in urine for the general population and for specific environmental and occupational groups as well as measurement of DDT and DDE content of complete prepared meals. These surveys have been correlated by obtaining as many of the samples as possible from the same individuals. For example, a number of the subjects in the work recorded here also contributed meals from their households for study of DDT and DDE ingestion rates. The results of the other segments of the complete DDT study will be published separately<sup>4–6</sup>.

A total of 10 individual and 4 pooled samples of human milk were analysed. The individual samples were collected in Chicago, Illinois (4 donors), Wenatchee, Washington (5 donors), and Phoenix, Arizona (1 donor). Multiple samples representing time-periods varying from 2 to 7 months were collected from three of the donors in Chicago

to determine the temporal variation in the concentration of DDT and DDE. The pooled samples were collected by the Fitzsimmons Army Hospital in Denver, Colorado. These samples were pooled from many (13 to 44) donors who were dependants of military personnel from various parts of the United States.

The samples from Chicago and Denver were obtained as the precipitate formed by the treatment of 1–2 l. of formalized milk using the method of Murthy *et al.*<sup>7</sup>. The filtrates had been used for determination of strontium-90 levels. These precipitates were provided through the courtesy of the Robert A. Taft Sanitary Engineering Center, Cincinnati, Ohio. The samples from Wenatchee and Phoenix were frozen as whole milk in plastic bottles until analysis. The sample from Phoenix had been formalinized prior to freezing.

Complete histories of exposure to pesticides were obtained from the donors of the individual milk samples. Three of the donors from Wenatchee lived in houses immediately adjacent to orchards that had been periodically treated with DDT for many years. However, no DDT was applied to these orchards during the period of milk collection. None of the other donors had any known exposures to DDT other than those characteristic of the general population (that is, consumption of small amounts of residue in the diet and occasional household use of sprays or aerosols containing DDT). It was not practicable to obtain the histories of exposure to pesticides from the women who contributed to the four pooled samples.

Aliquots (usually 100 ml. of milk) were analysed by a modification of the Schechter-Haller spectrophotometric method<sup>8</sup>. Even though the limited accuracy of this method for quantities of DDT and DDE less than 5 µg was realized, all samples which produced recognizable Schechter-Haller colours were accepted at their calculated values. In all but three of the samples analysed, visible blue, red, or intermediate colour was produced in the Schechter-Haller reaction.

All the values given in this article for total DDT-derived material (DDT plus DDE) have been expressed in terms of DDT equivalent. Numerically this is accomplished by multiplying DDE concentration by the factor 1.11. Values for DDE expressed as a fraction of total DDT-derived material were determined by use of the following formula:

$$\text{DDE (\% of total)} = \frac{\text{DDE (p.p.m. as DDT equiv.)}}{\text{DDE (p.p.m. as DDT equiv.)} + \text{DDT (p.p.m.)}}$$

Recent investigations have indicated that gas chromatographic techniques are able to detect smaller quantities of DDT and DDE and to distinguish more quantitatively the various isomers and ratios of isomers than is the colorimetric procedure<sup>8</sup>. Nevertheless, the Schechter-Haller method has been used for so long that it is important for purposes of comparison with earlier investigations for some additional data to be collected in this way, at least until there is more information based on the newer techniques<sup>9</sup>.

The concentrations of DDT and DDE in these samples of human milk are shown in Table 1. Whole milk contained an average of 0.08 p.p.m. DDT and 0.04 p.p.m. DDE based on the individual samples and 0.07 p.p.m. DDT and 0.10 p.p.m. DDE based on the pooled samples. The lipid fraction contained an average of 2.5 p.p.m. DDT and 1.4 p.p.m. DDE based on the individual samples and 3.5 p.p.m. DDT and 4.8 p.p.m. DDE based on the pooled samples. There is good correspondence between the DDT levels for these two types of samples; however, the DDE levels correlate less closely.

Data collected in the survey recorded here on the variation in the excretory level of DDT and DDE in

human milk over a period of time is shown in Table 2. It can be seen that there was little change in the excretory levels of DDT and DDE for each individual subject over the 2-7-month periods investigated.

The trend in the concentration of DDT in human milk in the United States between 1950 and 1960-61 is illustrated in Table 3. The mean DDT concentration was 0.13 in 1950 as compared with 0.07-0.08 p.p.m. in 1960-61. A comparison of the frequency distribution shows that there were fewer samples at the higher concentration levels in the later survey. Results of the earlier survey were not reported on the basis of lipid fraction nor was the DDE content of the milk determined. The range of values in the work reported here for both DDT (<0.01-0.22 p.p.m.) and DDE (<0.01-0.14 p.p.m.) is comparable with that for samples collected in California in 1962 (DDT, zero to 0.12 p.p.m.; DDE, zero to 0.25 p.p.m.)<sup>11</sup>.

Table 3. TREND IN THE CONCENTRATION OF DDT IN HUMAN MILK IN THE UNITED STATES

Mean concentration (p.p.m.)	0.13	0.08	0.07

It is of interest to compare the DDT and DDE levels in the fat moiety of human milk samples with the storage levels of these compounds in human body fat. In a recent investigation using analytical techniques comparable with those used in the work recorded here, storage levels of 6.8 p.p.m. DDT and 13.5 p.p.m. DDE in the extractable lipid fraction of human body fat taken from persons in the general population of the United States were found<sup>8</sup>. Thus, although concentrations in both tissues are of the same order of magnitude, DDT, and particularly DDE, levels appear to be somewhat lower in the fat moiety of human milk than in the extractable lipid fraction of human body fat. In the body fat, DDE represented 68 per cent of the total DDT-derived material, while in the milk DDE constituted 38 per cent (based on individual samples) or

60 per cent (based on pooled samples) of the total. The DDT levels in human milk from Hungary (3.3–6.8 p.p.m. in the lipid fraction)<sup>3</sup> are associated with an average DDT storage level in human body fat in that country of 5.7 p.p.m.<sup>10</sup>

Apparently, Hungary is the only country other than the United States for which values for DDT excretion in human milk have been reported. The values from Hungary for DDT in human milk (0.13–0.26 p.p.m. in whole milk) appear to be somewhat higher than the levels reported here or those reported by West<sup>11</sup> for the United States. In comparing DDT storage levels in human body fat from various countries, Quinby *et al.*<sup>3</sup> concluded that the level in Hungary equalled or exceeded that in the United States, while the concentrations were lower for other countries (Canada, Britain, France, and Western Germany) for which data were available.

The pharmacodynamic relationships of DDT intake, storage and excretion are incompletely understood, even in physiological situations in which the complicating factors involved in lactation do not occur. However, it can be calculated that a daily output of 700 g of milk containing 0.07 p.p.m. of DDT would account for a total daily excretion of about 0.05 mg of DDT by this route. This amount would account for about 125 per cent of the estimated daily dietary intake of DDT for the general population of this country (0.04 mg/person/day)<sup>4</sup>. Another fraction of the intake is excreted in the urine as DDA. The finding that the daily DDT excretion for lactating women may be slightly greater than the average daily DDT intake of the general population may, at least partly, be accounted for by the fact that during lactation women may eat greater than average amounts of food and/or may mobilize stored body fat. The constancy of the DDT excretion-level in milk for individual donors over the period of investigation may indicate that the relatively large amount of DDT stored in body fat serves as a 'buffer' to prevent large daily changes in excretion associated with possible daily changes in DDT intake.

Cows' milk also contains DDT; and here, too, as in the case of human milk, the average concentration apparently has decreased over the years. Comparable values for surveys of market milk showed that 67 per cent of samples were positive for one or more pesticides in 1955<sup>12</sup>, but only 33 per cent were positive in 1958<sup>13</sup>. Zweig *et al.*<sup>14</sup> have reported that cattle fed a diet containing 0.5 p.p.m. of DDT excreted less than 0.01 p.p.m. of the insecticide in their milk. However, at levels of 1, 2, 3, and 5 p.p.m. of added DDT, detectable residues of DDT, proportional to the level of contamination in the feed, were found in the milk of all animals. The cows fed DDT at the lowest level (0.5 p.p.m.) ate an average of 20 kg feed/day. Thus, their daily dose of DDT was 10 mg/day. Assuming that the average weight of these animals was 400 kg, it may be calculated that the dosage was 0.025 mg/kg/day. This dosage resulted in a DDT concentration of <0.01 p.p.m. in the milk of the cows. Even if these cows averaged 0.01 p.p.m. and excreted 15 l. of milk a day, the total DDT excretion in the milk would be 0.15 mg/day or about 1.5 per cent of the dose. Calculations of this sort made for a number of other investigations in which cows have been fed DDT-contaminated diets give results of the same order of magnitude, excretion rates ranging from 1.8 to 29.8 per cent of the daily dose<sup>15</sup>. There seems to be a tendency for a larger fraction of DDT intake to be excreted in the milk at higher dosage rates.

It is interesting to compare these values for the cow with those already given here for women. At a DDT dosage level of about 0.025 mg/kg/day, the cow excretes DDT in milk at a concentration of less than 0.01 p.p.m. and eliminates only about 1.5 per cent of the daily DDT intake in this way. However, at a DDT dosage level of about 0.0005 mg/kg/day, lactating women excrete DDT in milk at a mean concentration of 0.07–0.08 p.p.m. and eliminate about 125 per cent of the estimated average daily DDT

intake in this way. Thus, although the calculations for the cow are based on a higher daily intake of DDT, the cow excreted less DDT in the milk both on a concentration basis and calculated as a fraction of daily intake than did lactating women.

Turning now to the question of safety, it appears, from study of available cases of accidental or intentional ingestion of the compound, that the single oral dose of DDT that will cause poisoning in man is about 10 mg/kg<sup>16</sup>. The repeated dose of DDT that is harmful to man is unknown, but studies in volunteers<sup>17,18</sup> and in men with massive occupational exposure<sup>19</sup> show that adults can withstand without detectable injury 200 times the average dietary level of 0.18 mg/man/day that prevailed in 1953<sup>20</sup>. Furthermore, the general dietary level of DDT has now decreased to about 0.03\* (ref. 21) or 0.04 mg/man/day<sup>4</sup>. This amount of DDT corresponds to a mean concentration of about 0.02 p.p.m. DDT in the total wet diet of adults in the United States<sup>4</sup>.

The results presented here indicate that babies having human milk as their sole food source are exposed to a somewhat higher dietary concentration of DDT (0.07–0.08 p.p.m.) than is the general population (about 0.02 p.p.m.). Furthermore, the food consumption per unit of body-weight is higher for infants than for adults. If a 5 kg (11 lb.) infant consumed 0.7 l. of milk daily containing DDT at an average concentration of 0.08 p.p.m., the resulting dosage would be 0.0112 mg/kg/day. This value may be compared with the average adult dosage of 0.0005 mg/kg. Also, there is a considerable amount of evidence that young animals, including foetal ones, are somewhat more susceptible than adults to many chemicals including DDT<sup>22</sup>; however, the difference is only a few-fold. On the other hand, there is one report that a single oral dose of DDT was less toxic to young (2.4 h old) than to adult rats<sup>23</sup>.

Thus, the information at present available for man indicates that there is, for adults, a large safety factor associated with the use of DDT. For infants, the safety factor appears to be smaller. Continued research and surveillance of the exposed population should be carried out with particular attention being given to the health of infants to ensure that undetected toxic effects do not follow long-continued, low-level exposure to DDT and other persistent pesticides.

\* This value was not given in Mills's paper but can be calculated from his data.

# PROTEIN PRODUCTION BY LYMPH NODE CELLS OF RATS STIMULATED WITH PERTUSSIS VACCINE

By CHARLES E. SLONECKER and DR. WILLIAM O. RIEKE

Department of Biological Structure, University of Washington,  
School of Medicine, Seattle, Washington

RECENT investigations have emphasized that lymphocytes are of major importance in the initiation of the primary immune response to certain antigens<sup>1,2</sup>. Although it has been reported that small lymphocytes enlarge after antigenic stimulation<sup>3,4</sup>, and that larger lymphocytes in germinal centres proliferate and produce certain immunoglobulins<sup>4,5</sup>, little is known of the protein metabolism of the various sizes of lymphocytes during such responses.

A group of eight adult male Lewis rats was given  $3.2 \times 10^6$  (0.05 c.c.) inactivated pertussis cells (Lilly, V-1035 pertussis vaccine, fluid) subcutaneously in each hind footpad. Eight control animals received 0.05 c.c. of normal saline. Six hours after the footpad injection, both experimental and control animals received 6  $\mu$ c./g body-weight of tritiated methionine (sp. act. 191 mc./mole) intravenously. Experimental and corresponding control rats were killed at 1, 6, 12, 18, 24, 36, 60 and 80 h after injection of tritiated methionine. One popliteal lymph node was minced in rat serum for smears while the contralateral popliteal node was fixed in 10 per cent formalin for 3 $\mu$  paraffin sections. Autoradiographs of both smears and sections were made by techniques previously described<sup>6</sup> and were exposed for 2, 5 and 8 weeks.

A second group of adult male Lewis rats was antigenically stimulated and killed as described for the aforementioned animals. Both popliteal nodes were colorimetrically analysed for deoxyribonucleic acid (DNA)<sup>7</sup> and ribonucleic acid (RNA)<sup>8</sup>.

Following stimulation with pertussis vaccine, the popliteal nodes rapidly increased in weight. Quantification of DNA (Fig. 1) in the enlarged nodes indicated that this increase in weight was due to cell proliferation. Differential cell counts on smear preparations showed that this proliferation occurred principally in the lymphocytic series. There was also a slight rise in the number of reticular cells present in the popliteal nodes, but no appreciable change was observed in the plasma cell series.

Protein metabolism was analysed in each cell series and category by studying autoradiographs of node smears. Both the percentage of labelled cells and the grain density were determined. The most active cell type in metabolizing radioactive amino-acid was the large lymphocyte

(Table 1, Fig. 2). The stimulated large lymphocytes were much more heavily labelled per unit area than were the controls. Part of the labelling of stimulated large lymphocytes no doubt reflected only the normally occurring increases in cytoplasmic constituents prior to division. However, since control large lymphocytes are also known to be dividing<sup>9</sup>, the difference in labelling between stimulated and control cells suggested increased protein production and turnover in the stimulated cells. Further evidence of increased turnover of protein was seen from the decrease in label with reference to time (Fig. 2), which was greater in the stimulated large lymphocytes than in the corresponding controls. Many of the heavily labelled large lymphocytes in the stimulated animals appeared more basophilic than the large lymphocytes in control animals. This histochemical reaction also suggested increased protein metabolism. While the present investigation alone does not distinguish between a non-specific increase in protein metabolism in large lymphocytes and the production of specific immune substances, the work of others<sup>4,6</sup> has implicated this cell type in the production of immunoglobulins.

Fig. 2. The data in Table 1 are combined to show labelling patterns of pertussis-stimulated and control lymphocytes at intervals after a single injection of tritiated-methionine. Small lymphocytes: —, control; ---, experimental. Medium: ●—, control; ●---, experimental. Large: ▲—, control; ▲---, experimental.

Fig. 1. Colorimetric methods were used to show the quantity of DNA and RNA in popliteal lymph nodes at intervals after a single footpad injection of pertussis vaccine (experimental) or saline (control). Δ, DNA; ○, RNA; ---, experimental; —, control.

The second highest labelling intensities with tritiated-methionine were seen in the medium-sized lymphocytes (Table 1). Again it was noted that the stimulated cells exhibited more activity than the controls. Like the large lymphocytes, the greater labelling intensity in the stimulated medium lymphocytes may have been due in part to the synthesis of cellular constituents prior to division. However, previous investigations in this laboratory have shown that even in non-stimulated rats medium lymphocytes turn over protein more rapidly than may be expected from mitosis alone<sup>11</sup>, and since immune substances have been shown to be produced in stimulated medium cells<sup>4</sup>, it seems probable that the increased labelling

Table 1. LABELLING PATTERNS OF LYMPHOCYTES IN THE POPLITEAL NODE

60	38	4.9	37	4.0	40	2.9

The percentage labelled and average grain counts of all sizes of lymphocytes in stimulated and non-stimulated popliteal nodes are shown. Injections of pertussis vaccine (experimentals) or saline (controls) were made into the footpads 6 h before isotope administration. Other experiments have shown that 100 per cent of control lymphocytes may be labelled 1 h after isotope if a sufficient quantity of radioactivity is given.

reflected such a synthesis. The decrease in radioactivity was greater in stimulated medium lymphocytes than in the controls (Fig. 2), and this too suggested a turnover and/or secretion of proteinaceous substances early in the immune response.

The small lymphocytes labelled with the least intensity of all lymphocytic cells. However, as in the large and medium lymphocytes, the stimulated small lymphocytes labelled with greater intensity than the non-stimulated. Fig. 2 shows that after the first 12 h, non-stimulated small lymphocytes maintain a relatively constant labelling intensity. This is most probably related to the fact that non-stimulated small lymphocytes do not divide<sup>8</sup>. The slight rise in labelling seen in the first 6 h may be the result of heavily labelled medium and large lymphocytes dividing to form small cells. Fig. 2 also shows that, unlike control small lymphocytes, stimulated small cells decreased in labelling intensity during the first 18 h. This may have been the result of a decrease in the number of labelled small lymphocytes as these stimulated cells enlarged to form medium lymphocytes<sup>1-3,12</sup>.

Fig. 2 further demonstrates that, concurrent with the drop in the labelling of small lymphocytes, there was an increase in the labelling intensity of medium cells. This probably was due both to a division of labelled large cells to form medium-sized lymphocytes, and also to the enlargement of some heavily labelled small cells.

Nucleic acid analysis supported the autoradiographic evidence for increased protein metabolism in stimulated lymph node cells. Fig. 1 shows increases in both the amount of nodal RNA and the RNA/DNA ratio per cell.

The results of the labelling patterns of the reticular cells are shown in Fig. 3. The reticular cell series of the stimulated nodes showed only a slight increase in number and a moderate increase in protein metabolism. The decrease

Fig. 2. Labelling intensity of reticular cells in experimental and control popliteal lymph nodes is shown at intervals following the administration of tritiated-methionine. —, Control; ---, experimental

in some label throughout the experiment occurred in both experimental and control nodes. The moderate turnover of label as compared with the marked turnover in lymphoid cells suggests that reticular cells do not exhibit markedly increased metabolism following antigenic stimulation. This is not intended to minimize the role of the reticular cell in the immune response but does support the evidence that they do not function as stem cells<sup>10</sup> and also argues against these cells being primary producers of immune substances.

It is concluded that rat lymph nodes stimulated with pertussis vaccine exhibited a lymphocytosis without a concurrent plasmacytosis during the initiation of the primary immune response. During the lymphocytosis the stimulated lymphocytes increased in both RNA and protein synthesis. Because reticular cells show only a slight increase in number and a moderate increase in protein metabolism during the initial immune response, they do not appear to behave as stem cells or as producers of immunoproteins.

## ACTIONS OF SOME COAGULANT SNAKE VENOMS ON BLOOD PLATELETS

By M. G. DAVEY and E. F. LÜSCHER

Theodor Kocher Institute, University of Berne, Switzerland

RECENTLY, Nahas, Denson and Macfarlane<sup>1</sup> reported details of the coagulant actions of eight viper venoms. We have examined effects of six of these on washed human blood platelets. These actions on platelets were compared with those of thrombin, which is believed to be a principal agent in the formation and consolidation of platelet haemostatic plugs, and of thrombi, *in vivo*<sup>2</sup>.

The venoms used, and their coagulant properties, are listed in Table 1. The Russell viper venom was a commer-

cial preparation ('Stypven', Burroughs Wellcome). Other venoms were the crude preparations used in the coagulation studies<sup>1</sup>. Stock solutions of 1–2 mg/ml. were made in physiological saline solution buffered with tris (tris-hydroxymethyl-aminomethane) to pH 7.4; these were stored at –20° C and thawed and diluted as required. We also obtained a purified coagulant fraction of *A. rhodostoma* venom from Dr. M. P. Esnouf, as a solution of 120 µg/ml. in saline. This substance has a thrombin-like action on

Table 1. VENOMS STUDIED AND COAGULANT ACTIVITY

Venom	Factor X activation*	Thrombin- like activity*	Acceleration by platelets†
Russell's viper	++++	0	+++
<i>Bothrops atrox</i>	+++	+	+++
<i>Bothrops jararaca</i>	++	++	++
<i>Echis colorata</i>	++	0	+
<i>Anelastrolon rhodostoma</i>	+	++++	+
<i>Trimeresurus purpuromaculata</i>	0	+	±

† Of clotting of cell-free plasma.

fibrinogen, splitting off fibrinopeptides A and B, as well as a number of peptides not produced by thrombin<sup>3</sup>. Of the other venoms, that of the Russell viper contains an activator of factor X (ref. 4); that of *Bothrops jararaca* has been found to clot fibrinogen directly, but to remove only fibrinopeptide A in doing so<sup>5</sup>.

We determined fibrinogen clotting times using purified human fibrinogen, 98–99 per cent clottable<sup>6</sup>, 25 mg/ml. in saline, plus 0.025 M calcium chloride solution (0.1 ml. of each) and enough *tris*-saline to give a final volume of 0.5 ml. after addition of the venom solution tested and any other additions. The mixtures were incubated at 37° C, and coagulation times recorded. Plasma clotting times were determined by substituting pooled normal human plasma (which had been stored for some months at -20° C) for fibrinogen in this test system. Calcium was sometimes omitted. Inhibitors tested included 'Hirudex' (crude extract of *Hirudo medicinalis*; Laboratoires ANA, Paris) and heparin ('Liquemine', Hoffmann-La Roche, 5,000 units/ml.). Platelets to be added in coagulation tests were first washed as follows, and suspended in *tris*-saline buffer to a concentration of  $1-5 \times 10^8$  per ml.; 0.1-ml. aliquots of such suspensions were used.

Platelets were obtained as previously described<sup>7</sup> and washed three times after isolation from plasma: twice with 0.9 per cent sodium chloride (9 parts) plus 3.6 per cent trisodium citrate (1 part); once with *tris*-saline buffer containing 0.5 per cent glucose. They were resuspended in a minimum volume of *tris*-saline-glucose, in concentrations of 80–100 mg of protein ( $4-5 \times 10^8$  platelets) per ml.: protein was determined by the biuret method<sup>8</sup>.

For venom investigations, 0.4-ml. aliquots of such suspensions were placed in glass tubes; unless otherwise stated 5  $\mu$ moles of calcium chloride solution were added, followed by the substance to be tested, with sufficient *tris*-saline to bring the final volume to 1 ml. Inhibitors, when tested, were included in this volume. Tubes were incubated for 15 min at 37° C and the extent of macroscopic platelet aggregation, and of contraction of the formed aggregates, were recorded. Then 0.2 ml. of a solution of EDTA (disodium ethylenediamine tetraacetate, 0.077 M) was added, the tubes were placed in crushed ice, and their contents diluted to about 10 ml. with *tris*-saline. After centrifugation at 1,500g for 20 min in the cold the supernatants were separated, the platelets resuspended in a further 8 ml. of *tris*-saline, and both fractions extracted with 2 per cent (final concentration) perchloric acid in the cold. After further centrifugation the supernatants were neutralized with potassium hydroxide, and their ultra-violet absorptions determined at 260 m $\mu$  in a Beckman DU spectrophotometer. The proportion of the total absorbing material in each supernatant fraction was calculated.

In experiments in which it was desired to exclude ionized calcium from the incubation mixtures, the addition of calcium chloride was omitted. In its place were added 2  $\mu$ moles of the calcium-chelator EGTA (ethyleneglycol diaminoethyl tetraacetate, Geigy; 0.1 M solution of the sodium salt, pH 7.4).

The results of coagulation tests performed with the venom were compatible with the patterns of their coagulant activities shown in Table 1. The degree of acceleration of plasma clotting by the addition of platelets was

proportional to the amount of factor X activation produced by the venom tested.

In control platelet experiments, platelets incubated with calcium and buffer showed no macroscopic changes but lost some 20–30 per cent of their ultra-violet-absorbing contents to the supernatant. Thrombin (Hoffmann-La Roche; 63 N.I.H. units/mg), at a final concentration of 10 units/ml. caused aggregation within 1 min; contraction of aggregates followed within 2 min and was complete within 5. 60–70 per cent of total ultra-violet-absorbing material was in the supernatant. Spectroscopic investigations have established that this material is mainly adenine nucleotides<sup>9</sup>.

Table 2 shows the effects of the venoms studied at various concentrations. That of *T. purpuromaculata* was the only one the action of which was comparable to that of thrombin in all respects (venom concentrations of 20  $\mu$ g/ml. and above). The two *Bothrops* venoms caused platelet aggregation and nucleotide release without contraction, up to 80  $\mu$ g/ml. *E. colorata* and *A. rhodostoma* venoms caused slight aggregation and release only at 200  $\mu$ g/ml. The pure *A. rhodostoma* coagulant was without effect up to 24  $\mu$ g/ml. (equivalent to approximately 250  $\mu$ g crude venom<sup>3</sup>).

Russell's viper venom caused platelet aggregation only at the lower concentrations tested (5–20  $\mu$ g/ml.), but nucleotide release was observed with all concentrations tested. At 200  $\mu$ g/ml. its release effect was equivalent to that of thrombin. Unaggregated platelets which had been treated with Russell's viper venom were aggregated within 20 sec of the addition to them of thrombin (20 units/ml.) or of a saline extract of platelet protein (12 mg protein/ml.): this extract had no demonstrable coagulant activity. Such platelets were also aggregated, but less rapidly, by the addition of serum or fibrinogen, or of plasma in the presence of 'Hirudex'.

Calcium dependence of three venom actions was tested by replacing calcium in the incubation mixtures with EGTA. This inhibits platelet aggregation by thrombin almost totally, but nucleotide release only partially. The effects of *T. purpuromaculata* venom were similarly altered, but all actions of the *Bothrops* venoms were inhibited in the presence of the chelator (Table 3).

Table 2. ACTIONS OF VENOMS ON PLATELETS

Venom	Concentration $\mu$ g/ml.	Aggregation	Contraction of aggregates	% Nucleotide released

Further experiments were performed to characterize the active substance in *T. purpureomaculata* venom (Table 4). It proved to be non-dialysable (48 h against 100 volumes of Tris buffer, pH 7.4; or against 2 vol. of buffer when the buffer was tested for activity). It was not inactivated by heating solutions to 56° C for 30 min, but most activity was lost after 10 min at 100° C. Its activity has been found quite stable during storage of solutions for at least 2 months at -20° C and at least one month at 4° C. Its action was inhibited, but to a lesser extent than that of thrombin, by 'Hirudex' (0.1 ml./40 µg venom) and heparin (500 units/40 µg). The clotting activities of the variously treated venom solutions were similar to their activities towards platelets. Absence of residual thrombin-inhibiting activity in the venom-'Hirudex' mixture suggests that the venom, like thrombin, reacts with hirudin to form an inactive product.

We conclude, tentatively, that the coagulant and platelet-altering substance in *T. purpureomaculata* venom are the same. This factor differs from thrombin in the rate of its action on fibrinogen and its greater heat-stability. It is, on the other hand, similarly calcium-dependent in its action on platelets and is similarly inhibited by hirudin and by heparin.

In these studies the venom coagulant (*A. rhodostoma*) which we knew reproduced the effect of thrombin on fibrinogen failed to alter platelets. Venoms with a partial proteolytic effect on fibrinogen (*B. jararaca*; ? *B. atrox*) only partially reproduced thrombin's action on platelets. In contrast, *T. purpureomaculata* venom had a platelet effect quite disproportionate to the rate of its coagulant activity. Now, this venom may prove to have the same proteolytic actions on fibrinogen as does thrombin, but these must proceed so much less rapidly that other explanations need to be sought for the similarity of thrombin and venom actions on platelets. Thrombin is known to release some amino-acids and a few small peptides from fibrinogen, as well as the well-defined fibrin-peptides A and B (ref. 10). Other potential substrates of thrombin include the coagulation factors V (ref. 11), VIII (ref. 12) and XIII (ref. 13). Of these,

factors V (ref. 14) and XIII (ref. 15), as well as fibrinogen, are closely associated with platelets. One of these or a similar protein may prove to be the substrate of similar actions of thrombin and this venom coagulant.

Certainly, these observations make it difficult to entertain any longer the concept that thrombin acts on the fibrinogen of platelets just as it acts on plasma fibrinogen to induce platelet metamorphosis<sup>16</sup>. Other evidence against this concept has recently been brought forward<sup>17,18</sup>.

The action of Russell's viper venom in platelets deserves further mention. In this case, the release of platelet nucleotides is dissociated from platelet aggregation, even in the presence of calcium, when high concentrations of the venom are used. It has been shown that aggregation of platelets by thrombin is mediated by the adenosine diphosphate (ADP) it releases<sup>19</sup>; but aggregation by ADP alone requires a plasma co-factor<sup>20</sup>, whereas aggregation by thrombin does not, as these experiments illustrate. Platelets which have been exposed to Russell's viper venom retain their ability to aggregate when thrombin is added to them. The venom therefore does not destroy any substance essential for aggregation. A possible conclusion is that thrombin releases ADP and also a substance which is an essential co-factor for aggregation; while Russell viper venom releases nucleotide alone. Our experiments suggest that such a co-factor is present in the soluble fraction of platelet proteins, and in small amounts in plasma, in serum and in preparations of fibrinogen. It has not yet been identified.

We thank Prof. R. G. Macfarlane and Dr. M. P. Esmouf for supplies of the venoms, and Miss G. Baumlin for her assistance. The work was supported by the National Heart Foundation of Australia and by the Kommission zur Förderung der Eiweissforschung an der Universität Bern.

## ENVIRONMENTAL INDUCTION OF HERITABLE CHANGES IN *Nicotiana rustica*

By DR. J. HILL

Agricultural Research Council Unit of Biometrical Genetics, Department of Genetics, University of Birmingham

EVER since Johannsen<sup>1</sup> carried out his work with dwarf beans (*Phaseolus vulgaris*) it has been realized that the phenotype expressed by any given individual results from the joint action of its genotype and its environment. Normally the external environment has no permanent effect on the phenotypic expression of a lineage.

but there are two exceptions to this general rule, namely induced mutation and conditioning. Both of these are phenotypic alterations brought about by a specific set of environmental conditions and persisting even after the removal of these conditions. Induced chromosomal mutation occurs at random, however, whereas conditioning,

like most induced extrachromosomal mutations, is a non-random process which has been compared by Mather<sup>2</sup> to the phenomenon of paramutation found in maize by Brink<sup>3</sup>.

Since this article will be concerned primarily with conditioning, it is necessary to define this term at the outset. Conditioning can be regarded as the directed alteration in the normal development of the phenotype of an individual resulting from the action of external agents. Such an alteration may be temporary, that is, a phenocopy lasting only for the lifetime of the individual concerned, or it may be more permanent, the effect being transmitted from parent to offspring. Such a more permanent effect may nevertheless show a gradual diminution in its intensity over successive generations such as occurs, for example, with dauermodifications<sup>4</sup>. It may, on the other hand, remain undiminished even after several cycles of sexual reproduction. The effects observed by Highkin<sup>5</sup> when he grew inbred lines of peas under differing temperature régimes come into this last category, as do those recorded by Durrant<sup>6</sup> and Durrant and Tyson<sup>7</sup>, who used all possible

fertilizers for at least the preceding ten years. The experiment was laid out in a randomized block design with six replicates, and supplementary light was provided. Rosette diameter of the plants was measured at fortnightly intervals, while flowering time in days from an arbitrary date and final height in inches were also recorded. Analysis of the data showed that overall the most significant feature was the effect of potassium in increasing rosette diameter. Potassium also tended to promote flowering, but this effect just failed to reach significance at the 5 per cent level of probability, no doubt because of the high block interactions which were used as the estimate of experimental error. No significant differences occurred between the treatment groups in respect of final height. Plants grown on these different fertilizer treatments will be referred to collectively as the  $C_0$  generation. For each variety and within each treatment line three plants were chosen at random and selfed. The seed from these plants was harvested and used to grow out the  $C_1$  generation (that is, one generation removed from the original treatment) during the summer of 1963 (Fig. 1).

Fig. 1. Diagrammatic representation of the experimental procedure

combinations of nitrogen, phosphorus and potassium fertilizers to induce heritable changes in an inbred line of flax. Durrant was the first to emphasize the genetical significance of this phenomenon.

Following an earlier unsuccessful attempt to condition *Arabidopsis thaliana*<sup>8</sup>, an experiment was conducted to see whether heritable changes could be induced in inbred varieties of *Nicotiana rustica* using different combinations of fertilizer treatments. The varieties chosen were inbred when they were first obtained by Prof. Mather in the early 1940's<sup>9</sup>, and since that time they have been maintained by strict selfing for approximately twenty further generations. There can therefore be no doubt as to the inbred nature of the material involved. The first experiment was conducted in a glasshouse during the winter of 1962-63 using three varieties of *N. rustica*. These varieties were grown on soil taken from a set of lined plots which had been treated with the eight different combinations of nitrogen, phosphorus and potassium

The  $C_1$  generation was grown on an experimental area which had received a uniform dressing of complete fertilizer applied at standard agricultural rates (about 15 cwt./acre). Basically the experiment was arranged in plots within a randomized block design. Each plot contained an equal number of plants from each of the originally treated lines, the varieties being allocated at random to the plots and plants at random to positions within each plot. Only two varieties were grown in this experiment because the seed of the remaining variety failed to germinate satisfactorily. Seed from the various lines was sown in appropriately numbered paper pots containing John Innes No. 1 compost mixture. Two seeds were sown in each pot and after approximately a fortnight the seedlings were thinned out, leaving only the centre plant in each pot. This procedure was adopted in order to minimize the risk of conscious selection. Afterwards the plants were planted in the experimental field, still in their paper pots, in rows set 27 in. apart with 12 in.

between plants within rows. Again the characters recorded were plant diameter with time, flowering time and final height.

It became apparent from this experiment that one of the varieties had not been permanently conditioned by the original glasshouse treatment, for the differences seen in the  $O_2$  generation were no longer present in  $O_1$ . However, on analysis the remaining variety (V.16) did show highly significant differences between the treated lines for both flowering time and final height (Table 1). These proved to be significant even when tested against the differences between families within lines, that is, differences between the progeny of individual  $O_2$  plants accumulated over all 8 treatments. An orthogonal breakdown of the sum of squares between lines reveals potassium to have the most significant effect in promoting flowering. For height, on the other hand, practically all the comparisons are significant. If the treatments applied in this variety we would further expect a high correlation between the line means of the  $O_2$  and  $O_1$  generations for flowering time. The correlation is in fact 0.86 while the regression sum of squares of  $O_1$  on  $O_2$  is highly significant irrespective of which item in the analysis it is tested against. A similar expectation does not hold for height because the differences produced in the  $O_2$  generation were not significant at the 5 per cent level of probability.

Table 1. ANALYSIS OF  $O_2$  EXPERIMENT FOR V.16

Character Item	Flowering time D.F.	M.S.	Final height D.F.	M.S.
Between lines	7	1,175.00†	7	981.87*
Between families within lines	16	242.91†	16	284.99†
Error	634	17.35	632	12.90

\*  $P = 0.01-0.001$ .

†  $P = < 0.001$ .

At the end of 1963 individual plants within each of the eight original lines of V.16 were again selfed. The experimental design for the 1964 test of the  $O_2$  generation was essentially similar to that of the previous year except that the blocks were not divided into plots, the individual plants being randomized within the blocks. Again, the experiment was grown over a uniformly treated area, and as before flowering time and final height were recorded.

Analysis of the 1964 flowering time data indicates the presence of significant differences between lines and between families within lines when tested against the experimental error (Table 2). That the mean square between lines is not significantly greater than the mean square within lines is due solely to the erratic germination of one of the families within the phosphorus line. On removal of this family the between-lines item becomes highly significant when tested against the within-lines item. An orthogonal breakdown of the sum of squares between lines reveals a pattern similar to that which emerged from the  $O_1$  experiment. For flowering time the effect of potassium is the most striking, whereas for height practically every comparison proves to be significant. This similarity is borne out by the correlation between the line means of the  $O_2$  and  $O_1$  experiments, which for flowering time is 0.86 and for height is 0.92. The regression sum of squares for both characters is significant against whatever item in the appropriate analysis it is tested. Table 3 gives the line means for all the various generations and the ranking of the different treatment lines in each experiment. The marked reduction in the range between the earliest and latest flowering lines from the  $O_2$  to the  $O_1$  generation is not to be attributed to a diminution of the conditioning effect but rather to the very warm summer of 1964 which compressed the range of flowering time in all the many experiments carried out with *N. rustica* in this department. Height, which is less affected by temperature than flowering time, does not show a similar decrease; in fact, if anything, the difference between the tallest and shortest lines is greater in the  $O_2$  generation.

Table 2. ANALYSIS OF  $O_2$  EXPERIMENT FOR V.16

Character Item	Flowering time D.F.	M.S.	Final height D.F.	M.S.

Further experiments are being carried out, in particular  $F_1$  and  $F_2$  diallel crosses between the eight lines, to examine the within family variances, but this résumé of the results to date indicates that the changes produced by the application of different fertilizer treatments in an inbred variety of *N. rustica* must be heritable since they have now been transmitted through two generations without any further treatments being applied. The apparent diminution in the range of mean flowering times is, as we have seen, almost certainly due to meteorological differences between the two years. For height the changes have been maintained without any apparent diminution even though there were no significant differences between the original treated plants—doubtless because these were grown in the glasshouse where they barely attained one-quarter of their normal stature.

The causes of conditioning remain a matter of conjecture for the time being. From Durrant's work on flax some of the more obvious explanations can be eliminated, but evidence of a more positive nature is not yet forthcoming. One thing is clear, however. Heritable changes have not so far been induced in material or for characters which have been subject to deliberate and intense selection. Such attempts have always failed, whereas both flax and *Nicotiana*—which have proved conditionable—have undergone relatively little conscious selection. Presumably material which has been heavily selected has also been grown in the most favourable environments and any conditioning which might have taken place will have gone hand in hand with selection. Once induced changes of this type have occurred they may well be irreversible under the normal range of environmental conditions experienced by the plant. Thus one is forced to seek out as material suitable for conditioning those plant species which have not been the objects of artificial selection, while experimental convenience requires that they be either obligate inbreeders or else readily made to self-pollinate so that the nature of any induced changes may be demonstrated.

The precise form of any practical applications which conditioning may have for crop improvement cannot be foreseen at present. Its most likely practical use would be if some hitherto commercially unimportant species were to assume agronomic importance. But, in such circumstances, one presumes that conditioning would automatically occur as selection was practised on the material.

### Evidence that the Dark Areas on Mars are Elevated Mountain Ranges

SINCE the time it was definitely concluded that the dark areas on Mars were not large, open bodies of water, much speculation has occurred concerning the question as to whether these areas are elevated above or depressed below the bright desert regions.

Apart from seasonal polar rifts (for example, the Mountains of Mitchel) and brightening of certain areas (Hellas), which indicate the possibility of snow deposits on isolated peaks and high plateaux, there has been no direct physical evidence for the existence of extensive mountain ranges on Mars.

The planet is so far from Earth that even with the largest telescope under the best seeing conditions elevation differences could not be resolved easily, unless one knew exactly where to look. Lowell<sup>1</sup> long ago calculated that no mountains in excess of 2,500 ft. in height could have escaped detection. However, he seems to have assumed lunar type mountains, that is, having steep slopes and being large in extent, a type of mountain which would cast a well-defined and easily detectable shadow.

If we consider the long dark strip Sabaeus Sinus, which is about 400 km wide, to be a symmetric mountain ridge 3,000 m in height, it would only have slopes of about 1°. It is difficult to believe that a mountain ridge on Mars with a 1° slope could cast a shadow detectable from Earth. In any event, Sabaeus Sinus is aligned in an east-west direction and is bordered by dark areas to the east and to the west so that any shadows cast would fall on areas already dark in contrast.

It is therefore not unreasonable to conclude that the dark areas on Mars could be mountainous ranges of considerable height, but with gentle slopes.

In 1964 I began a statistical survey of localized white and yellow cloud occurrences to look for possible relations with topographical features. The formation of localized clouds on Mars is indeed a rare occurrence, and the literature survey therefore has been extended over observations of the past century in order to gain some reasonably meaningful information.

One of the most interesting results of this analysis is the fact that many white clouds are observed to form over bright desert regions bordering along dark areas and to remain stationary in these positions for some time.

Notable areas of these instances have been recorded by J. Focas and A. Dollfus<sup>2</sup> for the regions of *Edom* ( $\lambda=355^\circ$ ,  $\varphi=-10^\circ$ ) to the north of Sabaeus Sinus and for Deucalionis to the south of Sabaeus Sinus, although similar occurrences in other regions are not unknown. (Other instances of these occurrences have been observed in Libya, Isidis Regio, the borders of Margaritifer Sinus, over the central part of Mare Acidalium in the region of Achillis Pons, and in Zephyria as reported in a personal communication by J. Focas.) These white clouds form over the bright regions just mentioned but align themselves lengthwise adjacent to the dark area Sabaeus Sinus.

From polarization investigations Dollfus<sup>2</sup> has interpreted the curves for white clouds to be "... identical with that observed for ice crystal clouds". Therefore they are convective phenomena and are subject to a thermodynamic analysis.

In invoking an explanation for these phenomena, the theory of the formation of standing waves to the lee side

of mountain ridges developed principally by R. S. Scorer<sup>3</sup> has been used.

If a pressure gradient is aligned with an east-west mountain ridge, the air currents blowing perpendicular to the upwind side of the mountain will cause standing sinusoidal waves to form on the lee side. These winds are generally referred to as Föhn winds and have been extensively investigated in the mountainous Alpine ranges of Europe<sup>4</sup>.

A Fourier representation of the mountain profile (assumed symmetric) takes the form :

$$\zeta = \frac{a^2b}{a^2 + x^2} = ab \int_0^\infty e^{ikx} - kx \, dk \quad (1)$$

where  $b$  is the height of the mountain,  $a$  is the width of the profile at half-maximum measured in a direction  $x$  from the centre of the mountain, and  $k$  is the wave number. The mountain profile acts as a disturbance to the otherwise laminar flow which propagates itself upwards through the airstream.

The disturbance at some height  $z$  of the airstream away from its undisturbed state then is given by:

$$\zeta(z) = ab \int_0^\infty \frac{\zeta_{z,0}}{\zeta_{1,0}} e^{ikx} - kx \, dk \quad (2)$$

where the function  $\frac{\zeta_{z,0}}{\zeta_{1,0}}$  is derived from the vertical wind equation:

$$w'' + (l^2 - k^2)w = 0 \quad (3)$$

and is explained in detail in the works by Scorer<sup>3,7</sup> and summarized by Colby<sup>8</sup>.

If a parcel of air containing water vapour is carried along one of these airstreams and is raised along one of the sinusoidal disturbances to a height above the level of condensation, it will make itself visible as a cloud having the lens-shape of the sine wave at that point. These so-called lenticularis clouds are stationary and always form to the lee of mountains since that is where the sinusoidal pattern is strongly concentrated (Fig. 1).

Fig 1

With this as the explanation for the peculiar white cloud formations described on Mars, we must *a fortiori* believe that the dark areas are extended mountain ranges causing lee-waves to form whenever meteorological conditions are suitable.

The required horizontal pressure gradients are known to exist on Mars as manifested in Hess's now familiar isobaric map of the planet<sup>8</sup>. In addition, mapping of the tropical wind patterns by McLaughlin<sup>10</sup> reveals the possibility of Föhn winds in these regions.

Theoretically, then, equation (2) should be solvable for the altitudes of these ranges. However, it should be noted that deriving meteorological data for the planet Mars is an extremely difficult task and must of necessity be extended over many years of observations from which only average numerical values are obtained.

Treatment of equation (2) is being carried out in detail by me and results will be published in a paper at a later date. At least some idea of the magnitude of mountain heights on Mars is hoped to be obtained by this procedure in spite of the precariousness in using the numerical values derived from meteorological observations.

Nevertheless, it should be safe to accept these white cloud formations as physical evidence of the presence of mountain ranges on Mars, and it will be extremely interesting to see if this theory is corroborated by the photographs of Mars transmitted back to Earth by the *Mariner IV* space craft.

## ASTROPHYSICS

### Limits on the Density of Intergalactic Ionized Hydrogen

OBSERVATIONS of background radiation at radio frequencies can be utilized to place limits on the amount of ionized hydrogen which exists in intergalactic space. For this purpose, I have calculated the intensity to be expected at low frequencies from cosmic sources in an Einstein-de Sitter universe. Intergalactic matter is assumed to possess the following properties:

- (1) The electron kinetic temperature is independent of time, as suggested by the form of the cosmic energy equation given by Layzer<sup>1</sup>.
- (2) Intergalactic matter is pure hydrogen (that is, no other source contributes electrons).
- (3) The electron density has attained its equilibrium value for specified temperature and density.
- (4) The electron temperature  $T > 10^4$  °K (that is, hydrogen is ionized).
- (5) The electron temperature is much greater than the temperature appropriate to the radiation density.
- (6) The density of intergalactic hydrogen is a constant fraction,  $\chi$ , of the mean density,  $\bar{\rho}$ , that is:

$$\rho_H = \chi \bar{\rho} = \frac{\chi}{8\pi G k^2} \quad (1)$$

where  $\chi$  is  $\leq 1$  and independent of time.

The intensity is computed by means of the relation<sup>2</sup>:

$$I_\nu = c \int_0^t j(\nu, t') \left[ \frac{R(t')}{R(t)} \right]^3 e^{-[\tau(\nu, t) - \tau(\nu, t')] } dt' \quad (2)$$

where:

$$\nu' = \nu \frac{R(t)}{R(t')} \quad (3)$$

and  $j(\nu, t)$  is the emission coefficient per unit volume;  $R(t)$  is the expansion scale factor, proportional to  $t^{1/3}$ , for early stages of all relativistic evolving universes and at all stages of an Einstein-de Sitter universe;  $\tau$  is a dimensionless time variable analogous to optical depths:

$$\tau(\nu, t) - \tau(\nu', t') = c \int_{t'}^t K \left[ \frac{R(t)}{R(t')} \nu' \right] dt' \quad (4)$$

So long as the frequency  $\nu'$  corresponding to  $t'$  is so small that bound-free absorption is negligible and  $h\nu'/kT < 0.1$ , the optical depth can be represented by the analytic expression:

$$\tau(t) - \tau(t') = 1.589 \times 10^{11} T^{-1} \nu'^{-2} t'^{-2} \left( \frac{\alpha}{S} + 1 \right)^{-1} \chi^2 W$$

where:

$$W = \left[ \left( \frac{t}{t'} \right)^3 - 1 \right] \left[ \frac{5}{4} \ln \left( 1.545 \times 10^{11} \frac{T^2}{\nu'^2} + 1 \right) - \frac{5}{3} \left( \frac{t}{t'} \right)^3 \ln \left( \frac{t}{t'} \right) \right] \quad (5)$$

$\alpha/S$  is the ratio of the collisional-radiative recombination coefficient to the collisional-radiative ionization coefficient<sup>3</sup>. If one chooses values of  $T$  and  $\chi$  that produce the greatest possible optical depth for given frequency and red-shift, one finds from equation (5) that effects of intergalactic free-free absorption on discrete source spectra at frequencies greater than 10 Mc/s will not be noticeable at red-shifts less than about 80. A red-shift of 80 is significantly greater than the present largest known red-shift,  $z = 2.01$  (ref. 4). (Further details on the calculation of optical depth and intensity will be published elsewhere.)

We consider two types of emission: (a) free-free emission from ionized intergalactic hydrogen, and (b) emission from discrete, non-thermal extragalactic radio sources. The latter is represented by an empirical model of the evolution of radio-source luminosity obtained by Davidson and Davies<sup>5</sup> by fitting radio source counts. The following changes were made in the Davidson and Davies model: dispersion in source power at any given epoch was neglected, and no cut-off was introduced for the emission coefficient. (Davidson and Davies set the emission coefficient equal to zero for red-shifts greater than  $\delta^*$ ;  $\delta^* = 4.44$  in an Einstein-de Sitter universe.)

The intensity resulting from the combination of free-free emission and emission from non-thermal discrete sources is plotted in Fig. 1. Observed points are taken from the summary by Wielebinski and Yates<sup>6</sup> for  $\nu = 1-404$  Mc/s and from observations by Alexander and Stone<sup>7</sup> below 5 Mc/s. Wielebinski and Yates find that the observed background intensity can be fitted with a spectral index  $\alpha = -0.65 \pm 0.15$  throughout the range 18.3-404 Mc/s. A measurement of brightness temperature  $T_B = 3.5^\circ$  K at 4,080 Mc/s by Penzias and Wilson<sup>8</sup> indicates that, somewhere between 404 and 4,080 Mc/s,  $\alpha$  must become positive. Now, in general, the combined emission from discrete sources and from intergalactic  $H^+$  would yield a spectral index that is negative at low frequencies and positive at high frequencies, since the intensity due to discrete sources has a negative spectral index, while the intensity due to  $H^+$  has a positive spectral index  $\alpha = 1.1$ . One notices in Fig. 1 that if  $\chi = 1$  and  $T \geq 2 \times 10^4$  °K, the spectral index becomes positive at too low a frequency and the calculated intensity is too large to agree with observations at  $\nu = 100-400$  Mc/s. Also, it is evident

Table 1. THEORETICAL BRIGHTNESS TEMPERATURE AT 4,000 Mc/s

$T$ °K	Intergalactic contribution		Discrete source contribution $T_s$ with $\chi=0.1$ °K
	$T_s$ with $\chi=1$ °K	$T_s$ with $\chi=0.1$ °K	
$10^4$	6.3		
$2 \times 10^4$	9.3	1.6	0.065
$6 \times 10^4$	16.0	2.9	0.075
$2 \times 10^5$	28.2	5.3	0.087
$6 \times 10^5$	46.5	7.4	

from Table 1 that for  $T \geq 6 \times 10^4$  °K and  $\chi = 1$ , the predicted background brightness temperature is significantly greater than 3.5° K at 4,000 Mc/s. We therefore eliminate an Einstein-de Sitter universe with  $\chi = 1$  and  $T \geq 2 \times 10^4$  °K.

Both galactic and extragalactic sources may contribute significantly to the observed background intensity. There is some confusion at present about the existence and size of the galactic contribution. If we assume that the background is primarily the result of cosmic sources, we can place more stringent restrictions on the density of intergalactic  $H^+$ . If  $\chi = 1$ , the calculations for temperatures less than  $2 \times 10^4$  °K yield too little radiation at frequencies below 30 Mc/s. The best fit to the observed intensity in the range  $\nu = 5-100$  Mc/s is obtained for a value of  $\chi$  between 0.1 and 0.01. Over the frequency interval 1-100 Mc/s, the models corresponding to  $\chi=0.1$  yield spectra with indexes  $\alpha = -0.50$  to  $-0.57$ , slightly flatter than the observed spectrum (the theoretical spectra would be steeper if the time dependence of the discrete source luminosity were weaker than that derived by Davidson and Davies), and the contribution to the intensity from non-thermal discrete emission dominates the contribution from intergalactic emission.

The discrepancy between calculated and observed intensities below 3 Mc/s does not invalidate the general conclusion that the observed background at low frequencies can be attributed to the integrated effect of non-thermal discrete sources. This discrepancy may reflect either the crudeness of our model for discrete source emission or local galactic absorption. We assumed that the spectral index of a discrete source is independent of time and frequency, whereas it is very likely that discrete source spectra turn over at low frequencies due to internal processes such as synchrotron self-absorption and thermal absorption.

Fig. 1. Intensity versus frequency

As one can see from Table 1, agreement with the observed background intensity near 4,000 Mc/s is quite good for  $\chi = 0.1$ . Unlike the intensity at low frequencies, the theoretical intensity near 4,000 Mc/s results mainly from intergalactic emission.

Thus, with the same value of intergalactic electron temperature and density, we obtain general agreement with observation both near 4,000 Mc/s and in the range 4-100 Mc/s. We conclude that the density of intergalactic  $H^+$  is probably at least an order of magnitude smaller than the mean density of an Einstein-de Sitter universe, and that the spectrum of background radiation at radio frequencies may be the product of extragalactic sources.

I thank Prof. D. Layzer for suggesting this problem and for his advice. This work was carried out while I held a U.S. National Science Foundation co-operative graduate fellowship.

### Contribution of Characteristic X-rays to the Radiation of Solar Flares

ATOMS bombarded by energetic electrons may experience ionization through the loss of a K-shell electron. Part of the subsequent rearrangement of the ion to its ground-state involves the movement of an outer (usually an L- or M-shell) electron to fill the K-shell vacancy. The energy released in this transition appears in one of two forms. Either a photon is emitted (characteristic radiation) or one or more outer electrons are expelled from the ion (the Auger process). The purpose of this communication is to point out that characteristic X-rays emitted as a result of such inner-electron transitions may make an important contribution to the X-ray emission of solar flares. It is not yet known with certainty whether the radiation from flares in the  $\lambda\lambda$  1-3 Å region is predominantly of thermal<sup>1,2</sup> or non-thermal<sup>3</sup> origin. The detection of the characteristic radiation of iron atoms in the X-radiation from flares would indicate that non-thermal processes are important in the production of X-rays in this wavelength range.

Equation (1) gives the emission per unit volume due to collisionally excited characteristic radiation in the K-series lines of any atomic constituent of a gas:

$$\epsilon_{ch}(Z) = N_Z W_Z \hbar \nu_Z \int_{E_{min}}^{\infty} N_e(E) v_e(E) Q_Z(E) dE \quad (1)$$

dE erg cm<sup>-3</sup> sec<sup>-1</sup>

where:  $N_Z$  = number density of Z atoms;  $N_e(E)dE$  = number density of electrons of energy  $E$ ,  $E + dE$ ;  $v_e(E)$  = velocity of electrons of energy  $E$ ;  $Q_Z(E)$  = K-shell ionization cross-section;  $W_Z$  = K-fluorescence yield (fraction of K-shell ionizations which produce K-series photons);  $\hbar \nu_Z$  = energy of K-series photon;  $E_{min}$  = electron energy required to ionize K-shell. Most of the energy of these K-series

transitions goes into the  $K\alpha_1$  ( $K - L_2$ ) transition with lesser amounts going into  $K\alpha_2$  ( $K - L_3$ ) and higher order transitions. These lines are closely grouped, however, and in computing the total energy in the  $K$ -line they may be considered together, using the  $K$ -fluorescence yield for all transitions to the  $K$ -shell.

Little is known about the emission of characteristic radiation by partially ionized atoms. However, it seems unlikely that the loss of some, less than half, say, of the outer electrons of an atom would markedly affect the  $K$ -shell ionization cross-section,  $Q_K$ , or the  $K$ -fluorescence yield,  $W_K$ . This is because the energies involved in the inner-shell transitions are much larger than the energies involved in the removal of the outer electrons. In these computations the  $K$ -shell ionization cross-section formula of Arthurs and Moseiwitch<sup>4</sup> have been used. The cross-section is maximum for incident electrons with energies of three times the  $K$ -shell ionization potential.

If sizeable fluxes of non-thermal electrons in the 10–30-keV energy-range are produced in solar flares, as is indirectly indicated by the scintillation counter observations of Anderson and Winkler<sup>5</sup>, then these electrons will excite the inner-shell transitions which produce characteristic X-rays. The most interesting element for investigation is iron. It is relatively more abundant than other heavy elements ( $N_{Fe} \approx 8 \times 10^{-4} N_H$ ) and its characteristic radiation falls in the wave-length range ( $\lambda$  1–2.5 Å) responsible for the sudden disturbances of the lower ionosphere which accompany some flares<sup>6,7</sup>.

In order to evaluate the relative contribution of the characteristic radiation excited by non-thermal electrons it is convenient to compare this emission to the bremsstrahlung emitted by the same electrons at the same wave-length. Using equation (1) with  $W_{Fe} = 0.35$ ,  $h\nu_{Fe} = 1.1 \times 10^{-8}$  erg/photon, and neglecting the variation with electron energy of the parameters under the integral, we estimate the emission in the characteristic lines of iron (with an uncertainty of roughly a factor of three) to be:

$$\epsilon_{ch}(Fe) \approx 2 \times 10^{-10} N_e N_{Fe} \text{ erg cm}^{-2} \text{ sec}^{-1} \quad (2)$$

It is acceptable in this case to neglect the integration over electron energy since this dependence is not strong throughout the 10–30 keV region. Electrons of energy greater than 30 keV appear to be relatively few in number<sup>8</sup> and so contribute little to the excitation of characteristic radiation. For comparison with the bremsstrahlung emission from these same electrons we re-write equation (2) in terms of the hydrogen atom density,  $N_H$ :

$$\epsilon_{ch}(Fe) \sim 16 \times 10^{-10} N_e N_H \text{ erg cm}^{-2} \text{ sec}^{-1} \quad (3)$$

The standard formulae are used to calculate the intensity of the bremsstrahlung emission per Å from these electrons at the wave-length of the iron  $K$ -line assuming a gas consisting of 87 per cent hydrogen and 13 per cent helium. Again the result is not strongly dependent on electron energy, within the 10–30 keV energy range. The bremsstrahlung intensity is:

$$\epsilon_{brem}(\lambda = 1.9 \text{ Å}) \approx 35 \times 10^{-10} N_e N_H \text{ erg cm}^{-2} \text{ sec}^{-1} \text{ Å}^{-1} \quad (4)$$

We see from this comparison that if sizeable numbers of energetic electrons are created by a flare then the characteristic radiation from neutral or weakly ionized iron may make a substantial contribution to the X-ray emission of the flare in the wave-length interval around 2 Å. Furthermore, the iron  $K$ -line multiplet is only about 0.03 Å broad so the characteristic line should be distinctly observable above the bremsstrahlung continuum with a spectrographic resolving power of roughly 0.2 Å. Self-absorption of the characteristic radiation is negligible. The optical depth of the line at the level of the photosphere is of the order of 0.001.

Since the X-ray line emission in this spectral region provides a diagnostic tool to measure the relative roles of thermal and non-thermal processes in flares it is useful

to compare the features of the line spectra of the highly ionized atom FeXXV and the characteristic radiation of neutral or weakly ionized iron. FeXXV would be formed and excited in thermal regions with a very high ( $T_e > 10^7$  °K) electron temperature whereas the characteristic radiation of neutral or weakly ionized iron would evidence the injection of energetic non-thermal electrons into a relatively much cooler gas.

FeXXV is a helium-like atom and its resonance transition appears as a doublet ( $1s^2 1S_g - 1s2p^1P_1$  and  $1s^2 1S_g - 1s2p^3P_1$ ) at  $\lambda$  1.87 Å with a separation of 0.006 Å between the two components. Transitions at  $\lambda$  1.69 Å ( $1s^2 1S_g - 1s3p^1P_1$ ) and  $\lambda$  1.51 Å ( $1s^2 1S_g - 1s4p^1P_1$ ), as well as others of higher order, may also appear.

The characteristic spectrum of neutral iron is well known. The strongest component is  $K\alpha_1$  at  $\lambda$  1.932 Å with  $K\alpha_2$  appearing one-half as intense at  $\lambda$  1.936 Å.  $K\beta_1$  appears at  $\lambda$  1.906 Å with about 18 per cent of the intensity of  $K\alpha_1$ . Other (satellite) lines may appear with much fainter intensity depending on the local conditions of ionization.

I thank Dr. Paul Kelly, of Lockheed Missiles and Space Co., who performed the Hartree-Fock calculations yielding the energy-levels of FeXXV. Dr. R. G. Athay made the original suggestion that characteristic radiation might be of importance in solar flares. This work was begun at the High Altitude Observatory, Boulder, Colorado, under the support of contract NONr-393(07) from the Advanced Research Projects Agency through the Office of Naval Research; and was completed under the Lockheed Independent Research Program.

## RADIO ASTRONOMY

### A Model of the Quasi-stellar Radio Variable CTA 102

ACCORDING to Sholomitsky<sup>1</sup>, the quasi-stellar<sup>2</sup> radio source CTA 102 (ref. 3) has a variable flux density at 32.5 cm, the period being about 100 days. Sholomitsky takes this to mean that the source cannot be larger than  $\sim 0.1$  parsec, which is the distance light travels in one period. Since its angular diameter is not less than about  $0.01 \text{ sec}^{\circ}$ , he concludes that it must be closer than 2 Mpc, and is possibly inside our own Galaxy. However, Schmidt<sup>4</sup> has recently announced that the optical object identified with CTA 102 has a red shift  $z = \delta\lambda/\lambda$  of 1.037, and so is probably at a distance comparable with the radius of the universe ( $\sim 3,000$  Mpc).

Although it is by no means certain that the observed variations originate in the source itself, we wish to propose a model which assumes this, and is consistent with the red shift observations.

The model is illustrated in Fig. 1. The radio emission is produced in a spheroidal shell the axis of symmetry of which is approximately along the line of sight. (Shell models for radio sources have been discussed by several authors<sup>5</sup>, and spheroidal shells in particular by Layzer<sup>6</sup>.) The main part of the emission comes from the region ADB, and its spectrum is taken to have a peak at about 300 Mc/s (Fig. 2). The variable part is assumed to come from the disk-like region AOB, which is pulsating (perhaps as

Fig. 1. Proposed model of OTA 102

Fig. 2

a result of an explosion occurring at O, the effect of which may reach all parts of the disk at about the same time). When this region is compressed, the magnetic field strength will rise, the individual electrons will be accelerated by the betatron mechanism, and the radiated power will be greatly enhanced. When radiating at its maximum, it is required to emit  $\sim 25$  per cent of the total flux observed at 1,000 Mc/s in order to account for the observed variations (that is, its flux density must be  $\sim 2 \times 10^{-10}$  W/m<sup>2</sup>(c/s)). Its spectrum is taken to be as shown in Fig. 2. The total spectrum then agrees with the observed spectrum of OTA 102 (ref. 9).

The disk will have its minimum size consistent with the required flux if it is opaque at (proper) frequencies up to  $\sim 1,000 (1+z)$  Mc/s when compressed. Furthermore, if its emission is to vary with a (proper) period of  $100/(1+z)$  days, its thickness cannot exceed  $3 \times 10^{17}/(1+z)$  cm. The electrons which radiate at frequencies around 1,000  $(1+z)$  Mc/s have energies of  $\sim 2 \times 10^{-4} (1+z)^{1/2} H^{-1/2}$  ergs, each electron producing  $\sim 2.16 \times 10^{-23} H$  ergs/sec/(c/s) (where  $H$  is in gauss). If synchrotron self-absorption is occurring, the power radiated from the surface of the disk at this frequency is  $\sim 3 \times 10^{-4} (1+z)^{1/2} H^{-1/2}$  ergs/sec/(c/s)/cm<sup>2</sup>. The number density of these electrons is therefore  $\sim 5 \times 10^{-4} (1+z)^{1/2} H^{-1/2}$  per c.c., and their energy density  $\sim 10^{-3} (1+z)^{1/2} H^{-1/2}$  ergs/c.c. Allowing for the fact that they only contribute a few per cent of the particle energy density, and assuming that the total particle energy is comparable with the magnetic energy, we conclude that the magnetic field when the disk is compressed is  $\sim 5 \times 10^{-3} (1+z)$  gauss. A threefold increase in the field strength will probably be sufficient to produce the required increase of about 20 in luminosity at 1,000  $(1+z)$  Mc/s (though the exact factor depends on the energy spectrum of the electrons). The pulsations will be sufficiently rapid if the Alfvén speed  $\sim c$ , and this will be true if the particle density of the ambient gas does not exceed  $\sim 1$  per c.c.

The angular diameter of the disk when the magnetic field has the foregoing value is  $\sim 3 \times 10^{-3} (1+z)^{1/2}$  sec. (This assumes that the electrons are radiating incoherently.

If they were coherent the angular diameter of the source could be much smaller, which might permit its linear diameter to be  $\sim 0.1$  parsec, consistently with a large red shift.) It follows that:

$$r \sim 22.5 \frac{z}{(1+z)^{1/2}} \text{ parsecs}$$

in the steady state cosmology. (In the Einstein-de Sitter model this value must be decreased by a factor  $\sim 2$  if  $z \sim 1$ .) Estimating the average magnetic field over the whole shell as  $10^{-3} (1+z)$  gauss, we deduce from the occurrence of self-absorption below 300 Mc/s that, in the steady state model:

$$R \sim 225 \frac{z}{(1+z)^{1/2}} \text{ parsecs}$$

This estimate of  $R$  enables the parameter  $\eta$  to be determined, for since the disk must not deviate from the tangent plane at O by more than  $\sim 0.1/(1+z)$  parsec, it follows from the geometry that  $R \sim 2,500z^2/\eta$  and so  $\eta \sim 11z(1+z)^{1/2}$ .

If  $z \sim 1$  the dimensions are:  $R \sim 160$  parsecs,  $r \sim 16$  parsecs, and  $\eta \sim 15$ . The lifetime of the electrons is 50–100 years in the fluctuating region, and rather longer in the rest of the source. The total energy of the source is at least  $\sim 10^{47}$  ergs, of which  $\sim 10^{44}$  ergs is in the disk. The probability that the shell should be oriented so that the disk points towards us is about  $3 \times 10^{-4}$ , which implies that very few radio sources can conform to our model. This model enables us to make the following predictions:

(1) The amplitude of the variations depends on the frequency  $\nu$  of observation as follows:

$$\begin{aligned} & \sim 0 & 0 < \nu < 300 \\ & \sim 0.013 \left\{ \left( \frac{\nu}{300} \right)^{3.1} - 1 \right\} & 300 < \nu < 1,000 \\ & \sim 0.25 & \nu > 1,000 \end{aligned}$$

where  $\nu$  is in megacycles. Thus the observations of Caswell and Wills<sup>10</sup>, who found no variations at 178 Mc/s, are not necessarily inconsistent with Sholomitsky's observations.

(2) For  $300 < \nu < 1,000$  the intensity reaches a maximum in a time  $t(\nu)$  days, say, ( $t < 50$ ), and then remains constant for a time  $(100-2t)$  days (that is, while the disk is opaque to frequencies between  $\nu$  and 1,000 Mc/s). The rise-time  $t(\nu)$  is an increasing function of  $\nu$ , as illustrated in Fig. 3.

(3) The times at which the intensity is a minimum should be the same at all frequencies  $\nu > 300$  Mc/s, unless there is appreciable dispersion.

However, as regards (3), even if there is negligible dispersion in the source, there may be appreciable dispersion produced by ionized intergalactic gas<sup>11</sup>. At 400 Mc/s, for example, the resulting delay may be as large as 2 h. At this frequency our model predicts an increase in flux of more than 1 per cent in about 10 days following the minimum, so that an intergalactic delay might be detectable. Moreover, there may be, superposed on the main variation, an additional small amplitude variation of much shorter time-scale than 50 days, which might then be detectable when the main variation is at a minimum. It would therefore appear to be worth while to develop the sophisticated techniques necessary to detect the possible dispersion, and so to test the hypothesis that there is a significant ionized gas in intergalactic

Fig. 3. Time variation of flux density

space, and perhaps even to determine the scale-factor of the universe if other radio variables are discovered<sup>11</sup>.

We thank Profs. F. T. Haddock, A. Sandage and M. Schmidt for their advice. This work was begun while one of us (D. W. S.) was visiting the Department of Physics and Astronomy, University of Maryland, under National Aeronautic and Space Administration grant NAG 5860. He is grateful to Profs. H. Lester and G. Westerhout for their hospitality.

*Note added in proof.* It has been reported by W. A. Dent (*Science*, 148, 1458; 1965) that the quasi-stellar source 3C 273 (and possibly 3C 279 and 3C 345 as well) is variable at 8,000 Mc/s, and that again there is a discrepancy between light-size, red shift and angular diameter. However, the discrepancy is much less than for OTA 102, and a special geometry of the type considered here might be a possible explanation without leading to such an unfavourable probability factor.

## RADIOPHYSICS

### Spectral Variations of the Structure of the Radio Sources Cassiopeia A and Cygnus A

In a recent article, Ryle, Elmore and Neville<sup>1</sup> gave a beautiful synthesis of the brightness distributions associated with the radiation at 1,400 Mc/s from the radio sources Cygnus A and Cassiopeia A. No discussion was given in their article of the relevance of earlier observations at other frequencies. A comparison of the results of Ryle *et al.* with the original low frequency measurements highlights some interesting features of both sources and stresses the need for further measurements at even lower frequencies.

**Cassiopeia A.** The approximate circular symmetry of the Cassiopeia A source was determined by Jennison and Das Gupta<sup>2</sup> at 125 Mc/s. Later phase-sensitive measurements by Jennison and Latham<sup>3,4</sup> at 127 Mc/s showed that the diameter of the source in position angle 90° was 4.1 min arc, that the distribution was limb brightened more than the radiation from a uniformly illuminated disk (and therefore considerably more than that from a volume emissive sphere) and that there was a faint spur to the east which extended for 4 min beyond the limb when projected into position angle 90°. Concurrent optical observations by Minkowski<sup>5</sup> confirmed the optical diameter as 4.1 min and also showed a faint spur extending from the main body of the nebula in position angle 70°. The independent agreement on the existence of this spur lends considerable support to its reality, but though it may be marginally detectable in observations made by Conway<sup>6</sup> at 500 Mc/s in 1955, it has not been observed in later measurements at higher frequencies. The enigma has recently been discussed elsewhere<sup>7</sup>, wherein it was pointed out that if it resulted from material or shock waves propagated from the original explosion normal to the line of sight, the velocity of propagation would have to be in excess of 15,000 km/sec. It seems unlikely that the spur was a background feature, independent of the supernova remnant, or that the radiation could be so transient that

it faded before the measurements were made at higher frequencies. It appears to be more probable that the feature has a steep spectral index.

The Cambridge super-synthesis of Cassiopeia A at 1,400 Mc/s shows a break in the shell and a general reduction of brightness from the centre through the gap near the position angle 75°. Not only is there this diminution of brightness at this position angle within the nebula, but also a faint spur extending from the gap is marginally detectable in Fig. 4 of Ryle's paper. This latter feature would probably not be significant were it not for the earlier measurements. The optical filament to the extreme east of the nebula does not lie within the main contours of the nebula but appears to define the southerly limit of part of the flare. The breakaway of material in this sector might result from less opposition to the expansion by the ambient gas clouds, but this seems unlikely, for the general expansion of the main body of the nebula appears to be proceeding with remarkable symmetry, although, as Ryle points out, the intense peak to the west is diametrically opposite to the gap. A preferential ejection in the initial explosion could give rise to the spur, but it is not easy to see why the gap has remained open and why the optical and low-frequency radio emissions appear to be distributed along the spur. A later secondary explosion or flare is a possibility, but the ejection velocity must then be considerably in excess of 15,000 km/sec. Layzer<sup>8</sup> has suggested that axial expansions may be expected in many radio sources, but the spectrum may indicate that the electrons radiating in the Cassiopeia flare are less energetic than those in the shell.

The results of Ryle *et al.* support by inference the existence of the Cassiopeia flare, and the interpretation of the reason for its existence is clearly of considerable interest. Detailed measurements at low frequencies are very desirable to confirm the structure, polarization and spectral index of the flare, and, indeed, to see if the feature still exists.

**Cygnus A.** The resolution of the Cygnus A source into two major components by Jennison and Das Gupta<sup>2,3</sup> in 1952 showed that at a frequency of 125 Mc/s the separation between the two major components was approximately 85 sec arc along the major axis, the position angle of which was slightly in excess of 90°. Jennison and Latham<sup>4,5</sup> using improved techniques at 127 Mc/s then determined the apparent separation between the centres of emission as 83 sec arc along the major axis in position angle 97° and showed that the  $\alpha$  source, leading in R.A., was slightly the stronger. Later measurements (Rowson; Twiss, Carter and Little; Lequeux; Bracewell; Maltby, Moffet and others) were confined to high frequencies. In all these later measurements the major binary distribution was confirmed, with some disagreement over the brighter of the two components and a suggestion of a central component of different spectral index.

The measurements by Ryle, Elmore and Neville are in remarkable agreement with those of Rowson at 3,000 Mc/s<sup>6,10</sup>. The convolution of their detailed distribution with the angular distribution corresponding to a lower limit for the resolving power, as used by Rowson, smooths the weaker inner source into the profile of the adjacent major component and reduces the apparent spacing between the major components to a value closer to that obtained at 3,000 Mc/s. The position angle of the major axis in the Cambridge synthesis is identical to that found by Rowson.

The more interesting comparison is that with the one-dimensional synthesis and major axis determinations made by Jennison and Latham at 127 Mc/s. If the tertiary component has a steep spectral index the spacing may be reduced, but the position of the source at lower frequencies will no longer agree with that determined by Smith<sup>11</sup> unless a similar spectrally sensitive component appears to the east. There is a change of slope in the Cambridge profile at approximately 19h 57m 46s which may constitute

such a component. It is possible that both these inner components are enhanced at lower frequencies relative to the outer parts of the distribution. Ryle's synthesis shows a negligible central contribution at 1,400 Mc/s and underlines the need for detailed measurements with a high resolving power at frequencies below 125 Mc/s.

## PHYSICS

### Nature of the Spearpoints observed during the Combustion of Zirconium Droplets

PHOTOGRAPHIC time exposures of rapidly moving metal droplets which are burning luminously in a gaseous oxidizer often exhibit curious spearpoints. These streak images: (1) become less intense and gradually narrower; (2) suddenly intensify and broaden; (3) finally narrow again as they gradually extinguish altogether. The overall photographic trace resembles a pointed spear, hence the name.

Spearpoints are frequently observed among the sparks formed when metals are ground against an abrasive wheel<sup>1-4</sup>. Similar traces occur when particles of zirconium are ignited by flash heating<sup>5</sup>.

The work recorded here shows that the spearpoints associated with the combustion of zirconium droplets result from the solidification of molten spheres of slightly sub-stoichiometric zirconium dioxide. It follows that the sudden intensification of the photographic image is caused by an increase in the emissivity of the droplet of oxide as it solidifies.

Freely falling droplets of zirconium were formed and ignited by an intense pulse of light from a capacitor discharge lamp; the apparatus and technique, except for slight improvements, have been described previously<sup>6</sup>. The burning droplets were photographed by their own incandescence with a camera the shutter of which was opened electrically for 0.5 sec after the scattered light from the heating flash had extinguished. A typical spearpoint is shown in Fig. 1a, which was recorded with a droplet 525  $\mu$  in diameter burning in flowing oxygen at a pressure of 625 torr.

The characteristics of the spearpoints were examined by interposing an inclined glass plate in the droplets' path of fall. This is shown in Figs. 1b and c. Whenever it was placed above the level at which the image abruptly widened and intensified, the droplets adhered to the plate and continued to burn, as shown in Fig. 1b. But when the plate was inserted in the path below this level the glowing droplet bounced elastically from the plate and dropped into the bottom of the apparatus where it bounced several times again before extinguishing. This is shown in Fig. 1c. When the plate was placed very close to the shoulder of the spearpoint, within about 1 mm, semi-elastic deflexions occurred.

The most reasonable explanation of these phenomena is that the trace intensifies as the droplet solidifies. The partially elastic deflexions probably result from a droplet with a solid exterior and a molten interior.

When droplets burning, as in Fig. 1, were quenched in liquid argon 2-3 mm above the shoulder of the spearpoint,

Fig. 1. Time exposures of freely falling zirconium droplets burning in flowing oxygen at 625 torr, photographed by their own incandescence. Shoulders of spearpoints are indicated by arrows. Droplet diameter was 525  $\mu$ . Width of each photograph corresponds to approximately 7 cm. In a, the droplet falls freely, showing complete spearpoint. In b and c, glass plate has been inserted in droplet's path of fall above and below shoulder of spearpoint, respectively. Adherence to plate in b indicates molten droplet; elastic deflexion in c indicates solidified droplet.

their weights had increased 34-35 per cent. This corresponds to the composition range  $ZrO_{1.04-1.05}$ .

The composition is consistent with the colour of the quenched droplets, which were dark grey or black with faint grey striations. Droplets which were quenched 2-3 cm above and below the shoulder of the spearpoint were black and white, respectively. Zirconium oxide of the compositions  $ZrO_{1.03}$ ,  $ZrO_{1.04}$  and  $ZrO_{1.05}$  is black<sup>7,8</sup>,  $ZrO_{1.07}$  is dark grey<sup>9</sup>, and  $ZrO_{1.08}$  is white<sup>8</sup>.

It is concluded that the sudden intensification of the photographic traces is caused by the transition  $ZrO_{x-s}$  (liquid)  $\rightarrow$   $ZrO_{x-s}$  (solid), where  $x$  is of the order 0.03. This process should occur very close to the melting point of  $ZrO_2$ , which is 2,700°-2,800° C (ref. 10). It is unlikely that the chemical composition of the droplets will change significantly in the short time required to form the shoulder of the spearpoint. Likewise, the temperature of the droplets cannot change during a phase transition. Therefore the intensification of the photographic image must be caused by an increase in emissivity as the molten sub-stoichiometric oxide solidifies.

A similar explanation may apply to the spearpoints observed during the combustion of droplets of metals other than zirconium<sup>4</sup>.

I thank Mr. N. L. Richardson for his assistance.

### Nucleation of Freezing by Cavitation in Sub-cooled Bismuth and Gallium

In the article entitled "Nucleation of Freezing by Cavity Collapse and its Relation to Cavitation Damage"<sup>1</sup>, it was stated that there was experimental evidence to support the suggestion that freezing in substances such as bismuth, germanium, gallium and silicon (the freezing points of which diminish with pressure up to relatively high compressions) may not be nucleated by cavitation. The complete basis for this comment was not provided and it is clear that an additional explanation is necessary. To my knowledge, no experiments involving the use of ultrasonically generated cavitation have been performed on these substances in their sub-cooled liquid states. The statement was based instead on information regarding other forms of treatment that normally induce dynamic nucleation. Apparently both sub-cooled gallium<sup>2</sup> and bismuth<sup>3</sup> are known to be surprisingly immune to such treatment. I believe that all dynamic nucleation is due to cavitation. The behaviour of gallium and bismuth is taken, therefore, to indicate that they are immune to the nucleating effects of cavitation, no matter how it is generated. Such a conclusion is obviously open to debate. The real test would seem to lie in the ultrasonic cavitation experiments.

### Viscosity of Emulsions

An iterative process, using Vand's formula<sup>1</sup>, appears almost always to be successful in obtaining a linear plot of the results of measurements of the viscosity of emulsions at varying contents of the disperse phase. The process can be carried out conveniently by means of a high-speed computer, and results are given for three dispersions, of which two are bituminous.

There is a need for a linear plot of the results of the measurements of the viscosity of emulsions, using the concentration of the disperse phase, or the equivalent of this, as the independent variable. Vand's formula gives a relation between the viscosity of a suspension and the volume occupied by the continuous phase. If the reciprocal of the logarithm of the relative viscosity  $\eta_R$  is plotted against the volume concentration of the disperse phase, a

Fig. 1. Plot of  $1/(1.5 + \log \eta)$  against volume concentration—results from Vand (ref. 2).

Fig. 2. Plot of  $1/(0.0 + \log \eta)$  against volume concentration of the disperse phase—results from Black (ref. 3).

Fig. 3. Plot of  $1/(20 + \log \eta)$  against volume concentration of the disperse phase—results from Black (ref. 3).

plot can be obtained which is linear up to about 50 per cent concentration. If the disperse phase consists of spherical particles of nearly uniform size, it appears that the best straight line through the experimental points so obtained intersects the concentration axis at about 60 or 70 per cent volume concentration. The ordinate of the accompanying figures is:

$$\frac{1}{0 + \log \eta}$$

where  $\eta$  is the measured viscosity of the suspension in poises, and  $O$  is the quantity to be determined by iteration using some linearity criterion for the final plotted points.

The results of Vand<sup>1</sup>, which were obtained using a suspension of glass spheres in a solution of potassium iodide, are shown in Fig. 1, and indicate that a plot can be obtained which is closely linear. Fig. 2 shows results which were obtained from measurements of the viscosity of an anionic emulsion of bitumen particles with diameters varying from 3 to 6 microns<sup>2</sup>. This emulsion shows a variation in viscosity similar to that observed in the case of the suspension of glass spheres, except that the points diverge from a straight line at a lower concentration than those obtained from measurements on the suspension.

Measurements of the viscosity at varying concentrations of the disperse phase<sup>3</sup> were made on an anionic emulsion

which had a wide range of particle sizes (1 micron to 10 microns in diameter). The results are shown in Fig. 3. Emulsions with volume concentrations higher than those shown were not stable and measurements could not be made on them. The behaviour of this emulsion as shown by the results is totally different from that of the previous one. Only some of the particles appear to take part in resisting the applied shear stress, otherwise the straight line would point towards the 70 per cent point on the concentration axis. It is reasonable to suppose that the large particles are the ones which do so, and that the small particles occupy the interstices.

### Electron Transfer in Spherical Vacuum Chambers

In an effort to explain the breakdown of proportionality between ionization current and gas pressure in cavity ionization chambers, Greening<sup>1</sup> postulated the transfer of slow electrons between the chamber electrodes. Using an approximate formula for the energy distribution of these electrons, he analysed the behaviour of 'vacuum' chambers with planar, spherical and cylindrical geometries, and thereby accounted for the asymmetrical current-voltage characteristic reported by Taylor<sup>2</sup>. Greening noted that the characteristic is in general dependent on the directional distribution of the emitted electrons; but stated that the expressions derived for the case of spherical electrodes should be independent of this angular function. Burlin and Husain have recently adopted a spherical vacuum chamber in their experiments on electron transfer, and have compared their results with those calculated on the basis of Greening's semi-empirical theory.

Neither Greening nor Burlin and Husain<sup>3</sup> have taken into account the effect of the surface-potential barrier on the slow electrons (~ few eV) and the consequent nature of the angular distribution function. Haehenberg and Brauer<sup>4</sup> give a description of this in their review article on secondary electron emission. Electrons having energies very much greater than the barrier height will be affected to a negligible extent and their energy-angular distribution will remain unchanged. In this case one would expect an angular distribution symmetrical about the axis of irradiation, and Greening's theory would hold. However, low-energy electrons suffer a refraction at the medium/vacuum interface and the angular distribution will be symmetrical about the normal to the surface. The following abridged analysis illustrates the effect of this process on the characteristic of a spherical vacuum chamber, and also demonstrates the consequences of non-uniform radiation fields.

Let  $N(E, \omega) dE d\Omega$  equal the number of electrons per unit area per rad emerging from an irradiated electrode, which have energies between  $E$  and  $E + dE$  and directions in the element of solid angle  $d\Omega$  around the unit vector  $\omega$ . In the case of azimuthal symmetry, we can write:

$$N(E, \omega) dE d\Omega = \frac{2\pi \sin \theta}{4\pi} N(E, \theta) dE d\theta \quad (1)$$

where  $\theta = 0$  is the surface normal. Consider Fig. 1, which depicts two concentric spherical shells. In general the absorbed dose at any surface is a function of  $\varphi$ , that is,  $D_A(\varphi)$  and  $D_B(\varphi)$ , which take on known values according to the nature of the radiation field. The total number of electrons emitted from the outer sphere which are collected by the inner sphere in the absence of a potential difference is given by:

$$Q_{BA} = \int_0^\pi 2\pi b^2 \sin \varphi D_B(\varphi) d\varphi \int_0^\pi \int_0^{2\pi} \frac{1}{2} \sin \theta N(E, \theta) d\theta dE \quad (2)$$

Similarly, the transfer from inner to outer sphere is:

$$Q_{AB} = \int_0^\pi 2\pi a^2 \sin \varphi D_A(\varphi) d\varphi \int_0^\pi \int_0^{2\pi} \frac{1}{2} \sin \theta N(E, \theta) d\theta dE \quad (3)$$

The net loss of electrons by the inner sphere in the absence of a bias voltage is given by:

$$Q = Q_{AB} - Q_{BA} \quad (4)$$

The foregoing equations show that in general the characteristic of the spherical vacuum chamber does not intersect the origin. In the special case of a uniform radiation field and an energy-angular function separable into the form  $N(E) \cdot \cos \theta$ , the current will be zero at zero bias voltage. Hence the zero-voltage current intercept found by Burlin and Husain is a consequence of one or both of the following factors: (1) A non-uniform radiation field due to inverse square and exponential attenuation in the chamber walls. (2) A distribution function  $N(E, \theta)$  which cannot be separated into independent energy and angular functions of the type  $N(E) \cdot \cos \theta$ .

When the outer sphere is held at a positive potential with respect to the inner, equation (3) still holds. The analogous equation for  $Q_{BA}$  can be obtained by the method used by Greening. Referring to Fig. 1, a diameter such as  $X'OY'$  can always be drawn parallel to any direction of emission, and a parameter  $r$  thereby defined. By considerations of energy and angular momentum conservation, electrons from  $B$  will be captured by  $A$  when  $r \leq a\sqrt{1 - V/E}$ . Since  $r = b \sin \theta$ , this condition determines the upper limit of the integration over  $\theta$ .

Thus:

$$Q_{BA}(V) = \int_0^\pi 2\pi b^2 \sin \varphi D_B(\varphi) d\varphi \int_0^\pi \int_0^{\sin^{-1} \frac{1}{2} \sqrt{1 - V/E}} \frac{1}{2} \sin \theta N(E, \theta) d\theta dE \quad (5)$$

and:

$$Q(V) = Q_{AB} - Q_{BA}(V) \quad (6)$$

The integral equation (6) can only be solved for an energy distribution  $N(E)$  which is independent of the angle of emission, that is, a function of the form:

$$N(E, \theta) = N(E) \times f(\theta) \quad (7)$$

where  $N(E)$  and  $f(\theta)$  are functions of only  $E$  and  $\theta$  respectively. Furthermore, the form of  $f(\theta)$  must be known.

Fig. 1

In this special and rather unlikely instance an analysis of  $Q(V)$  will yield the function  $N(E)$ . In experiments on secondary electron emission, the source of secondary electrons is usually situated at the centre of a collecting sphere, and all electrons are emitted radially and experience the same retarding potential. The energy distribution measured in such experiments is the quantity  $\int_0^\infty N(E, \sim) d\Omega$ . Such an energy distribution cannot be

found by analysing the characteristic of the spherical vacuum chamber, and the advantages of such a chamber over a parallel plate arrangement are illusory.

The analysis given here is a corollary of my investigations<sup>1</sup> into the behaviour of a parallel plate vacuum chamber. I thank Dr. J. R. Greening for his advice, and the Faculty of Medicine of the University of Edinburgh for supporting the investigations.

### Response of Time-dependent Materials to Oscillatory Motion

A CONSIDERABLE amount of attention has been directed in the past to the rheological behaviour of suspensions of deformable particles when subjected to oscillatory motion, with the result that there is now a reasonable body of theory and experimental data relating to the gross behaviour. However, there appears to be little information available for suspensions of undeformable particles such as the clay-water system reported here, although they may exhibit very interesting behaviour.

As an illustration we consider an equation of state of the form:

$$P'_{ij} = 2\mu(t)\epsilon_{ij} \quad (i, j = 1, 2, 3) \quad (1)$$

where the total stress is given by:

$$P_{ij} = P'_{ij} + g_{ij}P \quad (2)$$

and  $P$  is an arbitrary isotropic stress,  $\epsilon_{ij}$  is the strain rate tensor.

In laminar shearing the time-dependent viscosity may take the form:

$$\mu(t) = \mu_0 + \int_{-\infty}^t \frac{df}{dI}(I[t'])M(t-t')dt' \quad (3)$$

$\mu_0$  is the initial viscosity,  $f(I)$  is a suitable function of the quadratic strain rate invariant, for example:

$$f(I) = 1 - \exp\left(-\frac{1}{2}\alpha\epsilon_{ij}\epsilon_{ij}\right) \quad (4)$$

and  $M(t-t')$  is a memory function defined by,

$$M(t-t') = \int_0^\infty \frac{B(\Pi)}{\Pi} \exp\left(-\left(\frac{t-t'}{\Pi}\right)\Pi d\Pi\right) \quad (5)$$

In equations (3) and (5)  $B(\Pi) d\Pi$  is the contribution to the viscosity deficit at the current strain rate  $\epsilon_{ij}(t)$  after an indefinitely long period at that strain rate by all the elements of flow with relaxation times between  $\Pi$  and  $\Pi + d\Pi$ .

It may be shown that if the memory of the material is short so that higher moments of the relaxation spectrum ( $Bn$ ) than the first are negligible where:

$$Bn = \int_0^\infty \Pi^n B(\Pi) d\Pi \quad (6)$$

then equation (3) takes on the simpler form:

$$\mu(t) = \mu_0 - R_1 f(I) + R_1 \frac{df}{dI}(I) \quad (7)$$

where:

$$\frac{d}{dt} = \frac{\partial}{\partial t} + u^i \frac{\partial}{\partial x^i} \quad (8)$$

It is noted that the relaxation spectrum need not be either wholly positive or negative.

Restricting attention now to oscillatory shearing motion in which the shear rate  $\dot{\gamma} = \dot{\gamma}_0 \cos \omega t$  and retaining only the first term in  $\dot{\gamma}$  in (4) then the shear stress  $\tau$  is given by:

$$\tau = \left[ \mu_0 - \frac{R_1 \sigma}{2} \dot{\gamma}_0^2 - R \sin(2\omega t + \phi) \right] \dot{\gamma}_0 \cos \omega t \quad (9)$$

It is clear from (9) that the shear stress may contain odd harmonics of the shear rate frequency. The viscous shear stress may be zero either when the shear rate is zero or when the viscosity is zero, that is:

$$\mu_0 - R_1 f(I) + R_1 \frac{df}{dI}(I) - \dots = 0 \quad (10)$$

An exactly similar argument applied to a time-dependent yield criterion shows that the shear stress may contain even harmonics from this source and the yield stress is zero under an analogous criterion to equation (10).

Fig. 1. Barol clay in distilled water (30 g/20 ml.). Shear amplitude, 0.141. (a) 0.0792 c/s, stress amplitude diminishes with time, single peak; (b) 7.21 c/s amplitudes of stress increase with time, multiple peaked. Apparatus, Weissenberg rheogoniometer; natural frequency of torsion head, 42.4 c/s.

Examples of the response of a clay-water system are given in Figs. 1 a and b. Horizontal displacement of the shear stress relative to the strain rate may be due to elasticity, or time-dependency of the viscosity or yield stress. It is interesting to note that at the low frequency the stress amplitude diminishes with time whereas at the high frequency the stress amplitudes increase with time, suggesting that the associated relaxation spectra may not be entirely positive.

A more comprehensive account of these phenomena will be published elsewhere.

## Occurrences of Sinoite, $\text{Si}_2\text{N}_2\text{O}$ , in Meteorites

THE recent discovery of the new mineral sinoite,  $\text{Si}_2\text{N}_2\text{O}$ , in the Jajh deh Kot Lalu enstatite chondrite<sup>1-3</sup> prompted a systematic search for this compound in the other fourteen enstatite chondrites at present known to exist in the world's meteorite collections (Abee, Adhi-Kot, Atlanta, Bethune, Blithfield, Daniel's Kuil, Hvittis, Indarch, Khairpur, Kota-Kota, Pillistfer, St. Marks, Saint-Sauveur, Ufana). Of these fourteen enstatite chondrites, three were found to contain sinoite. These three are the Hvittis, Ufana and Pillistfer stones. The appearance of

Fig. 1. Several crystals of sinoite (centre, light grey) from the Pillistfer enstatite chondrite. Grey main mass is enstatite, white is metallic nickel-iron. Reflected light

Fig. 2. Electron beam scanning pictures of sinoite,  $\text{Si}_2\text{N}_2\text{O}$ . These pictures are obtained by scanning a microscopically selected area of the sample with the electron beam and recording the characteristic X-rays from the spectrometers on an oscilloscope screen. Sinoite has high silicon and nitrogen and moderate oxygen contents. O-rich areas are enstatite ( $\text{MgSiO}_3$ ); Fe-rich areas are metallic nickel-iron. The apparent N $\alpha$  intensities on enstatite and nickel-iron are due to high background values at this wave-length

Table 1. COMPOSITION OF SINOITE,  $\text{Si}_2\text{N}_2\text{O}$ , FROM THE HVITTIS, PILLISTFER, UFANA AND JAJH DEH KOT LALU ENSTATITE CHONDRITES (Weight per cent)

Element	Hvittis	Pillistfer	Ufana	Jajh deh Kot Lalu
Silicon	56.7	56.8	57.1	56.6
Nitrogen	31.7	31.4	31.9	31.6
Oxygen	13.0	13.0	—	13.1
Total	101.4	101.2	—	101.2

the mineral in these meteorites is very similar to its appearance in the Jajh deh Kot Lalu enstatite chondrite. In reflected light, the crystals are distinctly lighter than the surrounding enstatite and are up to about  $200\mu$  in length (Fig. 1). Under electron bombardment in the electron microprobe, sinoite is easily recognized by its bright greenish luminescence. In each meteorite, ten different grains of the mineral were analysed qualitatively (Fig. 2) and quantitatively for silicon, nitrogen and oxygen by means of electron microprobe techniques using methods previously described<sup>4</sup>. The quantitative analyses were carried out using sinoite from Jajh deh Kot Lalu as a reference standard. The results of these analyses are summarized in Table 1. The chemical identity of the compound in the four meteorites is apparent.

At our request, Dr. B. Mason kindly investigated thin sections of the Hvittis and Pillistfer meteorites available at the American Museum of Natural History, New York. Dr. Mason found the optical properties of the mineral in Hvittis and Pillistfer to be identical with those of sinoite previously described from Jajh deh Kot Lalu<sup>5</sup>. Dr. Mason also pointed out that Lacroix<sup>6</sup> described the optical properties of an unknown compound found in 1905 in the Hvittis and Pillistfer stones. Lacroix, however, was unable to identify the mineral. From Lacroix's description of the optical properties, it appears that this compound and sinoite are identical.

We thank Dr. B. Mason for his advice and for supplying most of the meteorite samples. We thank Dr. J. Larsen-Badse and J. Erlichman for assistance in the microprobe work.

## Attenuation of Telesismic Body Waves

AT the Royal Society discussion on 'Recent Advances in the Technique of Seismic Recording and Analysis' (January 28-29, 1965), de Noyer directed attention to the difficulty of observing short-period (about 1-sec period) shear waves at angular distances in the range  $25^\circ < \Delta < 100^\circ$ . The following analysis suggests a possible reason.

Consider a solid possessing a complex rigidity modulus  $\mu$  but real bulk modulus  $k$  and density  $\rho$ . Such a material exhibits absorption of both compressional,  $P$ , waves and shear,  $S$ , waves, and we denote the corresponding specific attenuation factors<sup>1</sup> by  $Q_P$  and  $Q_S$  and the corresponding wave velocities by  $\alpha$  and  $\beta$ , respectively. Then the  $P$  and  $S$  parameters are related by the Poisson's ratio,  $\sigma$ , of the material, by the following equations:

$$\alpha^2 (1 - 2\sigma) = 2\beta^2 (1 - \sigma) \quad (1)$$

$$(Q_S/Q_P) = (4/3)(\beta/\alpha)^2 = (2/3)(1 - 2\sigma)/(1 - \sigma) \quad (2)$$

In the Earth, both  $\alpha$  and  $\beta$  are functions of the radius, and their ratio is not constant, that is,  $\sigma$  is also a function

of radius. However, for propagation in the mantle, which for  $\Delta < 100^\circ$  is the case in point,  $\sigma$  only varies between 0.25 and 0.30, so that for order of magnitude calculations it can be taken as constant and equal to 0.28.

The subsequent analysis is now considerably simplified because, accepting this model, the  $P$  and  $S$  waves from a seismic source both travel identical paths to the receiver. Our object now is to consider their relative attenuation.

For each element of path,  $ds$ , within the Earth the amplitude of the  $P$  wave of angular frequency  $\omega$  will be reduced by an amount  $\exp(-\omega ds/2Q_P\alpha)$ . To evaluate the effect over the whole path we need the detailed variation of both  $Q_P$  and  $\alpha$  with radius. However, in the absence of such data we can write the result of integrating the expression over the whole travel path as  $\exp(-\omega T_P/2Q_P^*)$ , where  $T_P$  is the travel time and  $Q_P^*$  the effective mean  $Q_P$  over the whole path. Similarly, for the  $S$  wave the attenuation can be written  $\exp(-\omega T_S/2Q_S^*)$ . But, since we have assumed a constant Poisson's ratio, both the  $P$  and  $S$  waves follow exactly the same path, so that:

$$\beta T_S = \alpha T_P$$

and therefore, from equation (2):

$$(T_S/Q_S^*) = (T_P/Q_P^*) (3\alpha^2/4\beta^2)$$

For the specific case  $\sigma = 0.28$  we have:

$$(T_S/Q_S^*) \approx 4.4 (T_P/Q_P^*)$$

At the Royal Society discussion, one of us (E. W. C.) presented results consistent with a value of  $T_P/Q_P^* \approx 1$  for signals recorded at teleseismic distances (from shallow events). Flinn and Archaambeau have computed  $T_P/Q_P^*$  as a function of distance, using a Gutenberg-Birch velocity structure and a  $Q_P$  structure derived, using equation (2), from the model  $F$  for  $Q_S$  given by Anderson and Archaambeau<sup>3</sup>. On the direct branch of  $P$ , beyond  $20^\circ$ , Flinn and Archaambeau's results lie close to  $T_P = 0.8 Q_P^*$ , in satisfactory agreement with Carpenter's results.

Using such values, it can be shown that at periods of 1-sec,  $S$  wave amplitudes are attenuated by a factor of  $10^4$  more than  $P$  wave amplitudes. At 6-sec period, where  $S$  waves are, in fact, often observed, the corresponding factor is only 5. The model thus seems adequate to explain the observations.

It seems clear from Anderson and Archaambeau's results<sup>3</sup> that the majority of the attenuation occurs in the low-velocity layer at depths of the order of 100 km.

It would thus appear that examination of  $P$  and  $S$  wave spectra from suitably chosen seismic events can prove of great significance in determining the lateral variability of the low-velocity layer.

## METALLURGY

### Evidence for a Ternary Phase in the Aluminium-Magnesium-Silver System

Polmear and Sargent<sup>1</sup> and Polmear<sup>2</sup> have recently reported that small silver additions will influence the age-hardening characteristics of aluminium-magnesium alloys. They show, for example<sup>1</sup>, that the precipitate in a wrought Al-7 wt. per cent Mg alloy is finer and more uniformly dispersed with resultant increase in hardening, on the addition of 0.5 wt. per cent silver, and they suggest

that there may be an interaction between the magnesium and silver atoms.

Recently, this effect has been investigated in this laboratory where a 0.3 wt. per cent silver addition has been made to a commercial-purity based Al-5 wt. per cent Mg alloy (99.5 per cent Al, 99.93 per cent Mg). Ageing curves were obtained at 150°, 175° and 200° C, and these closely followed those obtained by Polmear<sup>2</sup> (at 150° and 200° C) for an alloy of the same composition. At 200° C, the maximum hardness occurred between 1 and 10 days.

Transmission electron microscopy revealed that not only the size and distribution of the precipitate were altered, as had been shown by Polmear<sup>1</sup>, but also that the morphology of the precipitates was quite different. Fig. 1 shows an Al-5 wt. per cent Mg alloy aged 7 days at 175° C, and Fig. 2 the equivalent material containing 0.3 wt. per cent Ag. The areas shown are grain boundary regions, the boundary in both cases being on the right of the micrograph. The latter alloy was then aged for 32 days at 200° C or 3 days at 350° C to coarsen the precipitate particles. These gave diffraction patterns which could be indexed according to a body-centred cubic unit cell of approximately 14.4 Å. This cell closely resembles those of the ternary phases, Al<sub>3</sub>CuMg<sub>2</sub> and Mg<sub>11</sub>(Al,Zn)<sub>12</sub>, which both have body-centred cubic unit cells of 14.28 and 14.16 Å respectively<sup>3</sup>. It seems possible, therefore, that a similar phase may be present in the Al-Mg-Ag system based on an empirical formula Al<sub>10</sub>AgMg<sub>12</sub> (44.1 wt. per cent Al, 29.4 wt. per cent Ag, 26.5 wt. per cent Mg). A melt of this composition was prepared from super-purity materials and chill cast. The resulting alloy was very brittle and could be ground to powder. The X-ray powder diffraction pattern obtained confirmed the existence of a phase with a body-centred cubic unit cell of  $14.50 \pm 0.05$  Å. Electron probe microanalysis of a polished section of the alloy showed it was almost single

Fig. 1. Wrought Al-5 wt. per cent Mg alloy aged 7 days at 175° C [101] zone

Fig. 2. Wrought Al-5 wt. per cent Mg - 0.3 wt. per cent Ag alloy aged 7 days at 175° C [001] zone

phase with very little segregation. The composition of the main constituent was 43 wt. per cent Al, 29 wt. per cent Ag, 28 wt. per cent Mg.

The foregoing results establish that there is a phase in the Al-Mg-Ag system similar to the  $\text{Al}_2\text{CuMg}_4$  and  $\text{Mg}_{11}(\text{Al,Zn})_4$  ternary phases and it follows that this is the phase which was present in the Al-Mg-Ag alloy aged for 32 days at 200° C. This ageing treatment produces a slightly over-aged material but it seems probable that the precipitates which are present at peak hardness must be closely related to the same Al-Mg-Ag ternary phase. Thus it would seem that aluminium-magnesium alloys containing small additions of silver should really be regarded as ternary precipitation-hardening alloys.

### Oxide Films on Mild Steel

It is sometimes assumed that the oxide film formed on iron at room temperatures is uniform in thickness across a specimen, and that where several oxides exist together they are present as layers stacked neatly one above the other. In an electron microscope investigation of the oxidation of mild steel using oxide films stripped by the iodine/methanol technique<sup>1</sup> the only oxide that consistently conforms with this idea is magnetite,  $\text{Fe}_3\text{O}_4$ . Fig. 1 shows magnetite with its diffraction pattern on a film stripped from mild steel. The metal specimen was electropolished in a 5 per cent perchloric acid/95 per cent acetic acid mixture, washed in methanol and given no additional air exposure before the surface layer was stripped. It is interesting to note that these stripped oxide films remain quite stable if kept in a desiccator for a year and still give the same diffraction results after this length of time. Magnetite typically appears as an almost featureless layer, though

Fig. 1. Featureless iron oxide with diffraction pattern. Scale, 1  $\mu$ .

Fig. 2. Non-diffracting iron oxide. Scale, 1  $\mu$ .

with experience its presence may be recognized without examination of the very characteristic orientated arced diffraction patterns it produces. The (001) projection, as in Fig. 1, occurs most frequently although other orientations have been observed on the surface layers produced on thin foil corrosion specimens and there is evidence that the orientation changes from grain to grain. The usual difficulty in distinguishing between  $\text{Fe}_3\text{O}_4$  and  $\gamma\text{-Fe}_2\text{O}_3$  was experienced in this work<sup>2</sup> since these oxides have the same crystal structure and lattice parameters. It is noticeable that the (200) reflexions are absent and that no mixed index reflexions appear—these facts point to  $\text{Fe}_3\text{O}_4$ . There are, however, eight (311)<sup>3</sup> reflexions that would not be expected and these consistently appear with this type of pattern on foils as well as on stripped oxide films. They suggest that the film is of the order of one unit cell in thickness, approximately 10 Å, and that the reflexions could arise by streaking<sup>4</sup>.

After short air exposures, oxide often appears superimposed on the surface of the featureless magnetite in a form looking like a string of spherical beads (Fig. 2) each approximately 500 Å in diameter. This material frequently occurs in small discrete areas rather than a continuous layer. It gives no sharp diffracting spots of its own, only a diffuse pattern added to the magnetite arcs.

This oxide may be truly amorphous, or the lack of identifiable diffraction spots may be due to radial broadening because each bead is composed of smaller spherical particles. After prolonged exposure of electropolished and etched mild steel to air at room temperature without special precautions to exclude moisture (Fig. 3, three days' exposure), oxide growth consisting of large numbers of small crystallites approximately 100 Å in diameter is the commonest form encountered. It is usually possible to identify the oxide type from the ring patterns produced by these crystallites. Goethite,  $\alpha\text{-Fe}_2\text{O}_3\cdot\text{H}_2\text{O}$ , as shown here, is the one most frequently encountered in corrosion specimens although its physical form can on occasions be very different from the small crystals shown.  $\gamma\text{-Fe}_2\text{O}_3$  also occurs as small crystallites of similar size to those shown in Fig. 3 and gives a ring diffraction pattern. Even after three days of air exposure, however, the oxide layer does not appear to be of uniform thickness nor is the specimen surface completely covered with crystallites. There are still areas similar to Fig. 2 showing discrete patches of the non-diffracting oxide, featureless magnetite or no

Fig. 3. Crystalline iron oxide.  
Scale, 1 $\mu$

apparent oxide at all. It is considered that the detailed structure of the oxide film is of importance in deciding where corrosion will start and how it will continue when the metal is exposed to air or water.

### Failure of Stainless Steel by Intergranular Decohesion during Creep

In an experiment where some stainless-steel tubes had been ruptured by internal gas-pressure, failure was observed to have occurred by the nucleation, growth and impingement of intergranular cavities. An attempt has been made to relate this failure-mechanism with the observed dispersion in life-to-rupture. The tubes were of double vacuum-melted 20Cr-25Ni-niobium-stabilized stainless steel. Their nominal dimensions were 0.40 in. bore diam.  $\times$  0.015 in. wall thickness: they were made by extrusion and cold-drawing followed by external grinding. About 120 cap-ended lengths of the tubing were internally pressurized with 1,750 lb./in.<sup>2</sup> argon ( $\sigma_e = 2\sigma_s$ ) at 650°C in an atmosphere of carbon dioxide + 10 per cent carbon monoxide and their lives-to-rupture measured. Optical metallography revealed that intergranular decohesion had been nucleated at many sites and had spread until rupture was complete. A process-rate model of decohesion was constructed and this led to the following equation:

$$F = 1 - \exp \left[ \frac{-Kt^{m+1}}{m+1} \right] \quad (1)$$

where  $F$  is the fractional area of non-coherent grain-boundary at time  $t$ , and  $m$  should be 1.33.

Equation (1) is a special solution of the differential equation:

$$\frac{dF}{dt} = Kt^m(1-F)^n \quad (2)$$

Fig. 1. Experimental points and the theoretical line

For  $n > 1$ , equation (2) has the alternative solution:

$$F = 1 - \left[ \frac{K(n-1)t^{m+1}}{m+1} + 1 \right]^{1/(1-n)} \quad (3)$$

Taking  $F$  as equivalent to the fractional number of tubes which had failed up to a certain time in the experiment, the data were compared with equations (1) and (3): in the case of the latter values of  $K$ ,  $n$  and  $m$  were established by plotting  $\log(1-F)$  against  $\log t$  for large  $t$  and  $\log F$  against  $\log t$  for small  $t$ . These tests revealed that the data correspond closely to the values of  $m$  and  $n$  deduced from the process-rate model. Fig. 1 illustrates this: here the data points are plotted together with the theoretical line for  $m = 1.33$  and  $n = 1.0$ .

From a practical point of view the existence of a physically based distribution function is a valuable asset since it permits reasoned estimates of low failure-rates from necessarily limited experimental data. Arbitrary use, without theoretical justification, of a function (such as, for example, the log-normal distribution) which happens to fit the available data can produce serious errors of extrapolation.

The process-rate model which led to equation (1) also predicts the effects on  $F$  of variables such as stress, ambient pressure, temperature and grain-size. Preliminary comparisons of these predictions with experimental data have given encouraging results.

## CHEMISTRY

### Preparation of Thiazyl Fluorides

THE action of silver difluoride on tetrasulphur tetranitride has been shown to yield the thiazyl fluorides  $\text{SNF}$  and  $\text{SNF}_2$ , but little is known about the action of other fluorinating agents on sulphur nitride. We have examined the action of several liquid and gaseous fluorides on sulphur nitride, and also the reaction of sulphur tetrafluoride with ammonia.

In glass, selenium tetrafluoride reacts with sulphur nitride at  $-10^\circ$  to give thiazyl fluoride, NSF (15 per cent yield), thionyl fluoride, silicon tetrafluoride, and selenium. The reaction is incomplete even when the selenium tetrafluoride is in large excess, and some  $S_2N_4$  can always be recovered from the solid residue. Iodine pentafluoride behaves in a similar manner towards sulphur nitride; iodine is liberated, and a white solid of composition  $S_2N_4(NSF)_4$  is formed, which decomposes at  $50^\circ$  to give thiazyl fluoride. In contrast, sulphur tetrafluoride reacts only slowly under pressure with sulphur nitride, at  $180^\circ$  in a steel bomb, yielding a little thiazyl fluoride, and much larger proportions of nitrogen and sulphur. Antimony pentafluoride combines slowly with sulphur nitride at  $25^\circ$ , and more rapidly at  $100^\circ$ , to give a green solid of composition  $S_2N_4(SbF_6)_4$ , a behaviour which recalls the similar reaction with sulphur<sup>2</sup>. At  $145^\circ$  this adduct melts with decomposition, to give thiazyl fluoride (10 per cent), together with sulphur dioxide and silicon tetrafluoride. Vanadium pentafluoride, which has been reported to have strong fluorinating properties<sup>3</sup>, reacts with sulphur nitride, but volatile products are not formed.

Elementary fluorine has been reported to react with  $S_2N_4$  to give sulphur fluorides and nitrogen<sup>4</sup>, but we find that under very mild conditions at  $-75^\circ$ , in an apparatus similar to that used by Brown and Robinson to synthesize sulphur tetrafluoride<sup>5</sup>, thiazyl fluoride and thiazyl trifluoride, NSF, are formed in good yield.

Sulphur tetrafluoride reacts with ammonia. At  $-95^\circ$ , with ammonia in excess, the principal product is tetrasulphur tetranitride (70 per cent yield); if the temperature of the reaction is raised the yield of sulphur nitride decreases. At  $25^\circ$ , with the sulphur tetrafluoride in excess, in a flow system, thiazyl fluoride (20 per cent yield) is formed.

Anhydrous hydrazine reacts with excess of disulphur decafluoride below  $25^\circ$ , but the only volatile product is nitrogen, and none of the possible compounds with nitrogen-nitrogen or sulphur-sulphur bonds is formed.

### Separation of some Metals by Extraction-chromatography using New Neutral Phosphoro-organic Compounds

THE separation of metal cations by means of partition chromatography with reversed phases, known also as extraction-chromatography<sup>1</sup>, has recently been extensively applied in the radiochemical field. Studies of cation separation, using phosphoro-organic compounds by this method, have been carried out by Sikierski *et al.*<sup>2</sup>, O'Loughlin and Banks<sup>3</sup>, and others, besides ourselves<sup>4</sup>.

Recently the new neutral phosphoro-organic compounds like tetrabutylpyrophosphate (TBPP)<sup>5</sup> and a mixture of TBPP with tetrabutylhypophosphate (TBHP)<sup>6</sup> have been employed in the static and dynamic extraction of metals.

These compounds, synthesized by Michalski and Modro<sup>7</sup>, form complexes with metal salts similar to those of tri-*n*-butyl-phosphate (TBP). The partition coefficients of various metals using TBHP and TBPP as the complexing

agents depend, among other factors, on the concentration of mineral acids in the aqueous phase. This last dependence makes possible a separation of some cation mixtures.

0.5 g of the 1:1 mixture of TBHP and TBPP was adsorbed as a stationary phase on silica gel ('Hyflo Super Cell') doubly treated with dichlorodimethylsilane. The gel, of 0.08 mm grain diameter, filled a 120 mm column of glass tubing, 2.8 mm in diameter. The rate of drop formation (one drop of 0.03 ml in  $60 \pm 5$  sec) was controlled by pressure of the order of 0.1 kg/cm<sup>2</sup>. The measurements were performed by the radioactive tracer method. The concentrations of the solutions of salts labelled with radioisotopes used in the experiments are given in Table 1.

Table 1. CONCENTRATIONS OF THE SALTS

Salt	Concentration of metal-ion (M/L)	Radio-indicator
MnCl <sub>2</sub>	$2.5 \times 10^{-4}$	<sup>54</sup> Mn
FeCl <sub>3</sub>	$1 \times 10^{-4}$	<sup>59</sup> Fe
CoCl <sub>2</sub>	$1.2 \times 10^{-4}$	<sup>57</sup> Co
NiCl <sub>2</sub>	$2.1 \times 10^{-4}$	<sup>63</sup> Ni
CuCl <sub>2</sub>	$5 \times 10^{-4}$	<sup>64</sup> Cu
ZnCl <sub>2</sub>	$7 \times 10^{-4}$	<sup>65</sup> Zn
CdCl <sub>2</sub>	$2 \times 10^{-4}$	<sup>115</sup> mCd
Od(NO <sub>3</sub> ) <sub>3</sub>		
SbCl <sub>3</sub>	$4 \times 10^{-4}$	<sup>124</sup> Sb
TeCl <sub>4</sub>	$2.5 \times 10^{-4}$	<sup>127</sup> mTe
Tb(NO <sub>3</sub> ) <sub>3</sub>	$7 \times 10^{-4}$	<sup>160</sup> Tb
UO <sub>2</sub> (NO <sub>3</sub> ) <sub>2</sub>	$1.2 \times 10^{-4}$	<sup>235</sup> U

In order to determine the sorption conditions for the ions studied, 0.03–0.06-ml. samples of the solutions of salts of the investigated metals in HCl or HNO<sub>3</sub> of various concentrations were introduced in the column and then eluted with 9, 5, 1, 0.5, 0.1, and 0.01 N hydrochloric or nitric acid. The drops of eluate were collected on polystyrene foil and dried with an infra-red lamp. The activity of the initial solutions and the eluates was measured with a Geiger-Müller end-window counter 'AAH-55' type, measurements of the activity of radio-nickel were performed with a 2 $\pi$  flow counter, 'AET-60' type, and those of uranium with a scintillation counter, applying the method described previously<sup>8</sup>.

It has been shown in preliminary experiments that the divalent ions of transition metals are not adsorbed from the concentrated hydrochloric acid solutions and can be eluted in the first free volume of the column, whereas ions of trivalent iron become adsorbed and can be washed out with diluted HCl.

Fig. 1 shows a chromatogram of the separation of Mn (II), Co (II), Ni (II), Cu (II), Zn (II), and Cd (II) chlorides from Fe (III) ions, obtained on eluting the column first with 1.4 ml. of 9 N HCl and then with 0.9 ml. of 0.5 N HCl, which elutes the Fe (III) ions.

Fig. 1. Separation of (Mn, Co, Ni, Cu, Zn, Cd)—Fe.

In the case of Te (IV) and Sb (V) ions adsorption, it has been found that antimony is best adsorbed from 1 N hydrochloric acid, whereas tellurium ions are not adsorbed and can be eluted in the first free volume of the column. Fig. 2 gives the result of the separation of Te (IV) and Sb (V) ions after elution with 2 ml. of 1 N HCl, and then with 1.6 ml. of 0.1 N HCl, the latter desorbing the antimony ions.

Similarly, as in the case of hydrochloric acid, some metal ions are adsorbed from nitric acid solutions. Studies on metal ion separation using nitric acid as an eluant were carried out on sorption and desorption of cadmium, terbium, and uranyl nitrates. It has been proved that terbium, representing lanthanides, and cadmium are not adsorbed from 5 N HNO<sub>3</sub> solutions, whereas UO<sub>2</sub> (II) ions become adsorbed in these conditions.

Fig. 2. Separation of Te-Sb

Fig. 3. Separation of (Tb, Cd)-U

Fig. 3 gives a chromatogram showing the separation of Cd (II) and Tb (III) ions from UO<sub>2</sub> (II) ions, this being the result of elution with 1.6 ml. of 5 N HNO<sub>3</sub> and 2 ml. of 0.01 N HNO<sub>3</sub>, the latter desorbing uranyl ions.

We thank Prof. H. Niewodniczański for his interest in this work, Dr. M. Taube for the kind gift of some of the reagents, and Mr. T. Dabrowski for assistance.

### Polarographic Catalytic Properties of Cobalt-nitrohydroxylamine Complex

THE polarographic catalytic waves, observed by Brdička<sup>1</sup> in the complexes of cobalt or nickel solutions, are considered to be characteristic of organic molecules containing many active groups. It is accepted, in general, that the —SH group is the most specific for the catalytic process in a cobalt-containing medium, but there are also many other substances which do not contain sulphur in their molecular structure but which form catalytic waves: uric acid<sup>2,3</sup>, certain amino-acids<sup>4</sup> as histidine or lysine, glyceraldehyde, dihydroxyacetone<sup>4</sup> and also ethylenediamine<sup>5</sup>.

We have found that nitrohydroxylamine also forms catalytic waves in a cobalt-containing medium (Fig. 1). The formation of the catalytic wave is accompanied by a diminution of the wave due to the cobalt-nitrohydroxylamine complex. The concentration of this complex can be determined by the difference between the free cobalt wave and the wave formed on addition of the nitrohydroxylamine. The dependence of the catalytic wave of the cobalt-nitrohydroxylamine complex as a function of nitrohydroxylamine concentration is represented in Fig. 2 and shows the characteristic form of a catalytic wave. There is a marked analogy between the complex concentration and the catalytic wave-height. By plotting the

Fig. 1. Catalytic and complexing effect of nitrohydroxylamine;  $m = 2.75 \text{ mg s}^{-1}$ ,  $t = 5 \text{ s}$ ,  $A = 85 \text{ cm}$ , beginning at  $0.8 \text{ V}$ ,  $200 \text{ mV/sec}$ ,  $i_c$  = catalytic current,  $i_L$  = limiting current of active complex,  $i_{c_0}$  = the same current of inactive complex. (1)  $10^{-3} \text{ M Co}^{2+} + 0.025 \text{ M NH}_2\text{OH} + 0.05 \text{ M NH}_4\text{Cl} + \text{gelatine } 0.01 \text{ per cent}$ ; (2) the same solution  $+ 4 \cdot 10^{-4} \text{ M Na}_2\text{N}_2\text{O}_4$ .

Fig. 2. Plot of the catalytic and complex  $[\text{Co}(\text{N}_2\text{O}_2)(\text{NH}_4)]^+$  waves as a function of nitrohydroxylamine concentration; the conditions and the solution are the same as in Fig. 1. (Upper curve, catalytic wave; lower curve, active complex wave)

ratio of currents  $i_0/i_{00}$  ( $i_{00}$  is the limiting current of cobalt complex in absence of, and  $i_0$  the same current of the complex in the presence of, nitrohydroxylamine) as a function of the ratio  $[\text{Na}_2\text{N}_2\text{O}_2]/[\text{Co}^{++}]$  it is found that the catalytically active complex contains only one molecule of nitrohydroxylamine. The complex may be formulated as  $[\text{Co}(\text{N}_2\text{O}_2)(\text{NH}_4)]^+$ . It has also been found that a catalytic wave is formed in the absence of ammonium or any other indifferent electrolyte; in this case the catalytically active complex has the formula  $[\text{Co}(\text{N}_2\text{O}_2)(\text{H}_2\text{O})_4]^0$ . The molecular active group is then the chelate portion of the complex:

The same complex is formed with nickel, but this only exhibits a double diffusion wave and no catalytic wave is observed.

From these experimental results we can deduce the mechanism of the polarographic catalytic evolution of hydrogen and explain the role of the cobalt ion.

In order that catalysis shall occur it is necessary for the cobalt mono-chelate complex to have a more negative discharge potential than for the catalytic evolution of hydrogen. The decrease in the concentration of the active complex at the electrode surface is accompanied by a decrease in the current in the form of characteristic maxima for a catalytic current.

The value of the catalytic current is determined by two factors: (1) the concentration of the active complex; (2) the cobalt discharge potential in this complex. In the case of the nitrohydroxylamine there is a high concentration of active complex, but the cobalt discharge occurs at positive potentials ( $E_{1/2} \approx -1.6$  V; Fig. 1). With cysteine there is only a small concentration of active complex (practically unimportant in comparison with the total amount of cobalt), but the discharge potential, determined by extrapolation of the curve in Brdička tampon solution with cysteine, is very negative ( $E_{1/2} \approx -1.9$  V). This explains the low value of nitrohydroxylamine catalytic wave in comparison with the cysteine wave. The fact that the discharge potential of the nickel-nitrohydroxylamine complex occurs at an even more positive potential ( $E_{1/2} \approx -1.1$  V) explains the absence of the catalytic wave (begins at  $-1.35$  V, Fig. 1).

In connexion with the molecular structure of substances which exhibit catalytic waves in the presence of cobalt we have observed that it is essential for the molecule to contain at least two functional groups which are capable of chelate formation. One of these groups is capable of being adsorbed at the mercury electrode ( $-\text{SH}$ , for example), hence fixing the complex at the surface; the other accomplishes the function of a proton accepting-

donating group ( $-\text{NH}_2$  or  $-\text{COOH}$ , for example). The proton of this group is neutralized through the mediation of the complex. Also in the case of nitrohydroxylamine the chelation is produced between one adsorbing group

and one other protonated group  $=\text{N}-\text{OH}$ .

In conclusion we can state that no single functional group can show catalytic properties; it is essential that at least two functional groups be present in the molecule before catalysis can occur.

## Radiation Dosimetry with Sodium Cacodylate and Tris

DURING work on the irradiation of bakers' yeast, *Saccharomyces cerevisiae*, it was found that irradiation of the buffers, sodium cacodylate (sodium dimethylarsinate),  $(\text{CH}_3)_2\text{AsOONa}$ , and of tris (hydroxymethyl) amino-methane ( $=\text{tris}-2\text{-amino}-2\text{-hydroxymethyl}-1, 3\text{-propane-diol}$ ),

yielded substances giving positive Fiske-SubbaRow<sup>1</sup> and ninhydrin<sup>2</sup> colorimetric tests, respectively. Further investigations have been carried out to assess the value of these systems in radiation dosimetry.

Seven-ml. aliquots of sodium cacodylate (0.05 M, pH 5.5) were irradiated in  $17 \times 100$  mm polyethylene or polypropylene test-tubes<sup>3</sup>. This concentration and pH gave optimal colour development in the Fiske-SubbaRow<sup>1</sup> test. The test-tubes, in a wooden block accommodating 92 test-tubes in 4 rows, were passed through the 1.0 megacurie cobalt-60 source so as to receive  $10^4$ – $10^6$  rads of  $\gamma$ -irradiation with each passage through the source<sup>4</sup>. Radiation doses were monitored by ferrous sulphate-copper sulphate dosimeters<sup>5</sup>. After irradiation, a 0.5 ml. sample of sodium cacodylate was diluted with 8.5 ml. of water, and 2.5 ml. of reagent A (2.5 per cent ammonium molybdate in 5 N sulphuric acid) and 0.5 ml. of reagent B (filtered solution of 0.75 g 1-amino-2-naphthol-4-sulphonic acid + 1.5 g  $\text{Na}_2\text{SO}_4$  in 150 ml. water mixed with a filtered solution of 45 g of  $\text{Na}_2\text{S}_2\text{O}_8$  in 150 ml. water) were added. Reagents A and B are stable indefinitely when stored in the dark. The mixture was incubated in a water bath at 60° C for 10 min. Irradiated sodium cacodylate yielded, in this modification of the Fiske-SubbaRow<sup>1</sup> test, a blue colour resembling the colour of the phosphomolybdate complex formed with phosphorus. The intensity of the blue colour, read in a Klett-Summerson photoelectric colorimeter with a 660 m $\mu$  filter (Fig. 1), was proportional to dose up to a dose of about  $5 \times 10^4$  rads. The colour was stable for at least 7 h. The method was reproducible within 4–8 per cent (Fig. 1 indicates standard deviations based on 8 replicates). Repeated experiments at intervals over a 6-

Fig. 1. Sodium dimethylarsinate (cacodylate) as a radiation dosimeter. Irradiated cacodylate, 0.05 M, pH 5.5, was tested (ref. 1) and intensity of the blue colour was read (Klett 560 mμ). Each point represents the mean of 8 replications. Radiation at  $2.5 \times 10^4$  rads per passage through cobalt-60 source. Standard deviation ( $\sigma$ ) from mean is indicated; where  $\sigma$  is not shown, it was no greater than the radius of the circle representing the mean.

Fig. 2. Tris (2-amino-2-hydroxyethyl-1,3-propanediol) as a radiation dosimeter. Radiation at  $10^4$  rads per passage through a cobalt-60 source. Tris, 0.05 M, pH 7.0, was irradiated, and the ninhydrin-amino nitrogen colour (ref. 2) was read (Klett 560 mμ). Total Klett units = Klett reading  $\times$  sample dilution.

months' period gave Klett readings falling within one standard deviation ( $\sigma$ ) of the mean values shown in Fig. 1. The intensity of the blue colour depended only on total radiation dose and was independent of the dose per passage through the cobalt-60 source.  $\beta$ -irradiation\* of sodium cacodylate gave results which were similar to those obtained with  $\gamma$ -irradiation (same colour intensity for the same total dose). Colour intensity was independent of  $\beta$ -irradiation dose rate over a 4-fold range of dose rates.

The reaction mechanism for the conversion of sodium cacodylate to a compound giving a blue colour in the Fiske-SubbaRow is unknown. However, sodium arsenate gives a positive test (forming an arsenomolybdate complex) and the mechanism may involve oxidation (of the dimethylarsinate to arsenate) with accompanying demethylation, perhaps through the mediation of radiation-produced hydrogen peroxide. The postulated oxidation mechanism was given some credibility by the failure to obtain a positive (blue colour) test when sodium cacodylate was irradiated in the presence of a reducing agent such as ascorbic acid (ascorbic acid, added after irradiation,

does not interfere with development of the blue colour).

In experiments with tris (0.05 M, pH 7.0), 7.0 ml. samples were irradiated as already described here for sodium cacodylate. After irradiation, 0.2 ml. of sample, diluted so that the final Klett reading did not exceed 300, was mixed with 1.0 ml. of ninhydrin<sup>2</sup> reagent in a Klett tube, covered with a glass bead, and immersed in a boiling water bath for 20 min. After dilution with 5 ml. of 50 per cent *n*-propanol, the intensity of the purple colour determined at 560 mμ, and corrected for sample dilution, was proportional to the radiation dose (Fig. 2) up to at least 2.0 megarads.

The cacodylate and the tris systems appear to offer promise as simple radiation dosimeters. The range ( $5 \times 10^3$ – $5 \times 10^6$  rads), ease of preparation and of routine assay, low cost, and reproducibility of the cacodylate system make this a potentially useful system where megarad doses are common, as in food irradiation, or in cases where the increased ease of operation is more important than the greater precision of other chemical dosimeters.

### Whisker-like Crystals of Potassium Chloride

Porous glass<sup>1</sup> has pores of molecular dimensions (20–40 Å). During recent work on the use of porous glass in electrochemistry<sup>2</sup>, long, fibre-like crystals of potassium chloride were found growing from a dried-out porous glass-potassium chloride salt bridge. These crystals, of about 2 μ in diameter with lengths up to several centimetres, were weak but flexible. Among other compounds investigated sodium chloride, barium chloride, potassium nitrate, potassium chromate, copper sulphate and chrome alum showed the same phenomenon, but the resulting growth was slower than for potassium chloride, and the crystals were not so well defined. The rate of growth for potassium chloride crystals was about two centimetres per day. As there is interest in whisker crystals at present<sup>3</sup>, it was felt that this facile technique should be more widely known.

A plug of porous glass about 3 mm in diameter was sealed into 'Pyrex' tubing with 'Araldite' cement and

Fig. 1. Two weeks' growth from saturated potassium chloride solution.

Fig. 2. Potassium chloride fibres suspended in bromoform ( $\times a. 350$ )

Fig. 3. Potassium chloride whiskers growing from porous glass

ground flat by hand with water and corundum. The progress of the saturated potassium chloride solution through the dried porous glass plug could be seen as a sharply defined dark area which took about an hour to traverse the plug. The fibres could be observed, first as a white bloom on the plug, and later as a tight bunch of silk-like fibres resembling glass wool. These fibres bent into random configurations, due, it was felt, to imperfections in the sealing of the plug, and local air currents during crystallization. The crystals were usually grown in a normal laboratory atmosphere, but if the tube was placed in a desiccator with phosphorus pentoxide at atmospheric pressure, the phenomenon was inhibited. Marking the fibres with dye confirmed the assumption, made from general observations, that the crystals grow from the surface of the porous plug. Preliminary X-ray measurements of the potassium chloride fibres show that they have the normal crystalline form of face-centred cubic and that crystal growth is mainly along one main axis.

We thank Dr. I. D. Chapman, of Corning Glass, who kindly supplied the porous glass, and CIBA (A.R.L.), Ltd., Cambridge, who provided the cement (AF111/

HY111). We also thank Mr. G. B. Ansell for carrying out the X-ray measurements.

## BIOCHEMISTRY

### Induction of Tyrosinase in Higher Fungi

TYROSINASE is a common enzyme in mycelia and fruit bodies of several fungi. In contrast to laccase it is a typical endoenzyme which is not excreted into the culture medium. In some fungi its occurrence is inconstant and dependent on the stage of development of the mycelium. Whereas in *Phellinus laevigatus*, *Inonotus cuticularis* and *I. obliquus* tyrosinase can be found in young mycelia, in *Phellinus ribis* and *Gloeoporus adustus* its activity increases with the ageing of the hyphae. In some fungi (*Fomes marginatus*, *Leninus lepidus*, *Piptoporus betulinus*) tyrosinase is only present under special cultural conditions, but it can be induced by several chemicals, which are not substrates for this enzyme.

*Fomes marginatus* (strain 16a Eberswalde) proved a suitable test-organism because its mycelia grown on malt solution contain almost no tyrosinase activity. Addition of phenol, catechol, *p*-oxibenzoic acid and protocatechuic acid in final concentrations of  $5 \times 10^{-3}$  M did not induce any enzyme formation or any significant change in the growth rate of this fungus. Catechol was decomposed by the mycelia without formation of tyrosinase. Tyrosine was also ineffective.

A strong tyrosinase induction could be obtained by the addition of some metabolic inhibitors to the culture fluid (Table 1). Lower concentrations were often more effective than higher ones. In some cases the dry weight of the mycelia decreased due to a toxic effect on the fungus, but enzyme induction was not correlated with mycelium autolysis. Strong toxicity due to high concentrations, or a combination of different inducing toxins, inhibited the formation of the enzyme. Besides that, induction of the enzymes could be brought about not only by compounds which had a stimulating effect on the mycelium growth (with arsenate dry weight reached 132 per cent of the controls) but also by many that did not.

To determine whether the increase in activity was due to a mere liberation of the enzyme in the cell or to synthesis of a new protein, the effect of pentachlorophenol (PCP)—a strong inductor—was combined with that of actinomycin D, a specific inhibitor of RNA metabolism (the antibiotic was kindly supplied by Prof. Horváth, Budapest).

Table 1. TYROSINASE ACTIVITY (COLOIMETRIC UNITS) OF *Fomes marginatus* AFTER APPLICATION OF DIFFERENT METABOLIC INHIBITORS. CONTROLS WITHOUT ACTIVITY. (LUTHARDT)

Fig. 1. The effect of actinomycin D ( $7.5 \times 10^{-5}$  M) on the induction of tyrosinase by pentachlorophenol (PCP) ( $1 \times 10^{-4}$  M) in *Fomes marginatus*.

The results are shown in Fig. 1: With PCP a strong tyrosinase induction could be obtained, but this decreased on addition of actinomycin D to that level, which was reached by addition of the antibiotic alone. The controls contained no tyrosinase activity. The results show that actinomycin D inhibits tyrosinase induction by PCP to a high degree. This process seems, therefore, to be a real enzyme induction bound to an active protein metabolism. That actinomycin alone provoked a tyrosinase activity may be due to a liberation of a bound or inactive form of the enzyme, which was demonstrated by Horowitz and San-Chiun Shen<sup>2</sup> and by Esser<sup>3</sup>. The weight of mycelia decreased on addition of PCP during the first two days but recovered thereafter. Actinomycin brought about no additional inhibition of growth so that an excessively strong toxic effect can be excluded.

As can be seen from Table 1, a wide spectrum of substances is able to induce the formation of tyrosinase in *F. marginatus*. It is difficult to find a common basis for an explanation of this effect. Most of the inducers are able to inhibit the oxidative phosphorylation or respiratory processes (Krebs cycle) in fungi (2,4-dinitrophenol, PCP,  $\gamma$ -thujaplicine, arsenate ( $\text{Lyr}^4$ )). Oxytetracycline seems to have a similar effect in higher doses, because it liberates organic bound phosphate in yeast ( $\text{Lyr}^4$ ). *p*-Chloromercuribenzoic acid inhibits several dehydrogenases of the Krebs cycle. The weak effect of Na-azide, a known uncoupling reagent, is due to its low stability. Potassium cyanide, malonate and chloramphenicol were also inactive (probably for the same reason), whereas fluoroacetate had a strong inducing effect. It would therefore seem that a disturbance of the oxidative metabolism, especially of the ATP-formation (provided it is not too severe), leads to an enzyme induction. At present it is difficult to say whether this depends on the liberation of an internal inducer (an increased content of tyrosine in the mycelium could not be demonstrated), or whether the tyrosinase induction is bound to the abolition of a metabolic repression. By this we mean that the synthesis of the enzyme commences when a number of factors in the general metabolism have been satisfied, and these may vary from species to species. This would explain the appearance of the enzyme in young or old mycelia and in fruit-bodies. A very similar process seems to be the induction of laccase ( $\text{Lyr}^4$ , Fah-

raus<sup>5</sup>). It is possible that the formation of these unspecific enzymes is not bound to the presence of a specific inducer, but is regulated by the situation of the metabolism. Probably this mode of induction of tyrosinase is not restricted to fungi, but may also occur in higher plants where tyrosinase activity often increases in the region of sublethal injuries as part of a defence mechanism. It is worth mentioning that the enzyme is able to detoxify some of the inducing poisons, for example, PCP, oxytetracycline, thujaplicines ( $\text{Lyr}^{4,6,7}$ ). Whether this mechanism operates *in vivo* and is of importance for the fungus is not yet quite clear.  $\beta$ -Thujaplicine, on the other hand, is one of the most effective inhibitors of tyrosinase activity (Luthardt<sup>8</sup>).

### Selective Inhibition by Aldehydes of Streptokinase Activation of Plasminogen

Using synthetic substrate *p*-tosyl arginine methylester (TAME) and lysine methylester (LMe), Ablondi and Hagan<sup>1</sup> observed that plasminogen incubated in 50 per cent glycerol phosphate solution lost proactivator activity and gained spontaneous plasmin activity. Kline<sup>2</sup> examined pseudoglobulin (acid-extracted) plasminogen under the same conditions and found no decline in proactivator activity during the spontaneous activation process. We repeated these investigations with euglobulin (tricalcium phosphate-extracted) plasminogen and we examined the effects of lysine and glyceraldehyde on the system.

We incubated 10 mg/ml. of euglobulin (euglobulin plasminogen was obtained from Cutter Laboratories, Berkeley, California) or pseudoglobulin plasminogen in 50 per cent glycerol with 0.01 M phosphate buffer at pH 7.4, 37° C. The pseudoglobulin plasminogen gained spontaneous activity, without losing proactivator activity as assayed on TAME<sup>3</sup>, LMe<sup>4</sup> and casein<sup>5</sup> (Fig. 1). The euglobulin plasminogen also gained spontaneous activity, but lost proactivator activity. Three other properties of

Fig. 1. Effect of incubation in 50 per cent glycerol-phosphate solution (pH 7.4, 37° C) on the spontaneous plasmin activity (■), 100-μ streptokinase-induced plasmin activity (▲), and activator activity (●) of acid-treated plasminogen.

euglobulin plasminogen changed: (a) the rate of migration on immunoelectrophoresis changed; migration was as an  $\alpha_1$ -globulin instead of an  $\alpha_2$ -globulin. (b) Precipitation by streptokinase was no longer possible. (c) Caseinolysis by activated plasminogen was no longer inhibited by excess amounts of streptokinase. We concluded that the physical chemical properties of acid-extracted plasminogen were more stable in 50 per cent glycerol than those of euglobulin plasminogen.

This loss of proactivator activity (and other properties of euglobulin plasminogen) might have been explained by either a change in conformation of the enzyme or a reaction of plasminogen with an impurity in glycerol. Physical measurements of conformation revealed no change in optical rotation or viscosity. Therefore, we concluded that conformational changes were not causing the loss.

Two different lots of glycerol<sup>8</sup> were examined for compounds with reactive aldehyde groups by both the Fehling and Schiff tests<sup>9</sup>. The tests were positive. Therefore, glyceraldehyde, 0.001–0.01 M, was added to the plasminogen-glycerol system, and the effects observed after 6–12 h in this system were identical with those observed after 7 days in glycerol alone (Fig. 2). Lysine inhibited the effects of glyceraldehyde (Fig. 3). We concluded that glyceraldehyde selectively inactivated proactivator by reacting with its amino-groups (for example, glucose amine  $\text{NH}_2$ ,  $pK$  6.5, lysine  $\text{NH}_2$ ,  $pK$  10.1) and that this phenomenon was inhibited by compounds such as lysine, the amino groups of which had a  $pK$  sufficiently low to compete with the protein for aldehyde groups at  $pH$  7.4. Because the loss of proactivator activity and changes in physical chemical properties were accelerated

in the glycerol-glyceraldehyde system and because of the presence of aldehydes in glycerol we concluded that this might be the mechanism by which euglobulin plasminogen lost proactivator activity during 'spontaneous' activation in glycerol. It should be emphasized that glyceraldehyde produces a bovine type of plasmin from a human (SK-reacting) type.

### An Unstable Ribonucleic Acid in Normal Human Erythroblasts

It is now well established that the primary information required for protein synthesis is sited on DNA. The mechanism whereby, in animal cells, this information is conveyed and elaborated, so that protein synthesis may occur, is still uncertain.

The existence of a metabolically labile RNA in the nucleus of many animal cell types has been repeatedly observed by various techniques<sup>1,2</sup>. Polyribosomes have been shown to be directly responsible for protein synthesis<sup>3</sup>, and in this connexion an RNA fraction, similar to bacterial messenger RNA, because of its variable molecular size and high metabolic instability, has been isolated from the polyribosomes of rat liver<sup>4</sup>. Recently, another RNA messenger fraction has been isolated from the cytoplasm of rat hepatocytes<sup>5</sup>.

However, the results of some experimental observations are difficult to reconcile with the concept that the information required for protein synthesis in animal cells is obtained through a mechanism akin to that of bacteria, that is, through a continuous flux of labile RNA molecules, which are synthesized on the DNA model. It has been shown, for example, that the RNA present in reticulocytes, which are known to synthesize haemoglobin, is stable<sup>6</sup>. Furthermore, while the main site of protein synthesis appears to be located in the cytoplasm, no definite proof has yet been brought forward, as Harris has recently pointed out<sup>7</sup>, to show that transfer of RNA takes place from nucleus to cytoplasm. This author has been able to provide evidence that the greater part of the unstable RNA in the nuclei of some animal cells may be degraded without simultaneously affecting the rate of protein synthesis<sup>8</sup>.

The introduction of actinomycin D has provided a new and extremely useful tool for the study of RNA metabolism. This substance, by inhibiting the synthesis of all types of DNA-dependent RNA<sup>9</sup>, is ideally suited for assessing the rate of RNA degradation, especially in experiments at the cellular level, which are greatly influenced by the intracellular pool of metabolites and the re-utilization of turnover products.

A first series of experiments on the RNA metabolism of normal bone marrow cells, studied by means of actinomycin D, has already been reported elsewhere<sup>9</sup>. The purpose of the present communication is to describe the findings of some further experimental work on the RNA

Fig. 2. Effect of incubation in 50 per cent glycerol-phosphate solution (pH 7.4, 37° C) on spontaneous plasmin (■), 100-μ streptokinase-induced plasmin (▲) and activator activity (●) of euglobulin plasminogen and euglobulin plasminogen with 0.02 M glyceraldehyde

Fig. 3. Effect of incubation in 50 per cent glycerol-phosphate solution (pH 7.4, 37° C) on the spontaneous plasmin (■), 100-μ streptokinase-induced plasmin (▲) and activator activity (●) of euglobulin plasminogen and euglobulin plasminogen with 0.07 M lysine

and protein metabolism of normal human erythroblasts, using tritiated precursors for autoradiography, and actinomycin D. Our studies were undertaken to obtain additional information on the following points of the RNA and protein metabolism of erythroblasts: (a) the relationship between the rates of RNA and protein synthesis in the various stages of maturation of the red cell series; (b) the rate of labelled RNA degradation; (c) the effect of RNA inhibition on the rate of protein synthesis.

$^3\text{H}$ -uridine was used as an RNA precursor and  $^3\text{H}$ -leucine as a protein precursor (Radiochemical Centre, Amersham). The uptake of leucine may be taken to indicate the synthesis of a polypeptide chain<sup>10</sup>. So far as  $^3\text{H}$ -uridine uptake in nuclear RNA is concerned, its complete inhibition in erythroblasts, previously treated with actinomycin D<sup>9</sup>, seems to suggest that true RNA synthesis is taking place and not just a simple binding of terminal groups belonging to soluble RNA. Experiments were carried out on the bone marrow of three individuals with no haematological disorder.

To study the relationship between rates of RNA and protein synthesis, bone marrow cells were incubated for 1 h at 37° C with  $^3\text{H}$ -uridine and  $^3\text{H}$ -leucine at a concentration of 1  $\mu\text{C}/\text{ml}$ . and afterwards smeared on gel slides. For the purpose of differentiating between DNA and RNA labelling, cells before contact with the Kodak 'AR 10' films were treated for 2 h with a solution of DNase ('Sigma', 0.1 mg/ml.) in *tris* buffer<sup>11</sup> containing  $\text{MgSO}_4$ . After an appropriate period of contact, the autoradiographs were developed and fixed, and counterstained with May Grunwald-Giemsa stain. At least 40 cells for each different maturation stage were examined, and the standard error did not usually exceed 15 per cent. In Fig. 1 the rates of RNA and protein synthesis, indicated by the average grain counts, are shown in relation to the maturation stage of the red cell precursor. It is apparent from the diagram that the rate of RNA synthesis decreases as maturation progresses, but at a faster rate than that of protein synthesis.

The rate of RNA degradation was measured using the inhibition of the synthesis of all types of RNA induced by actinomycin D. The suspension of bone marrow cells was incubated for 1 h with  $^3\text{H}$ -uridine at a concentration of 1  $\mu\text{C}/\text{ml}$ . and a proportion of the cells was immediately smeared. Afterwards, in order to inhibit as rapidly as possible labelled RNA precursor uptake, not only actinomycin D was added to the cultural medium as in previous experiments<sup>9</sup>, but the cell suspension was centrifuged and the cells re-suspended in Gey's medium containing actino-

Fig. 2. Decrease of RNA radioactivity, after addition of actinomycin D to the medium in erythroblast precursors previously incubated for 1 h with tritiated uridine.

mycin D at a concentration of 10  $\mu\text{g}/\text{ml}$ . and non-labelled uridine  $10^{-3}$  M. Smears were made after 30, 60, 120 and 180 min, and autoradiographs were prepared after incubation with DNase.

The results are summarized in Fig. 2, which clearly shows that in proerythroblasts and in early and intermediate erythroblasts, at least two metabolically different types of RNA are synthesized, one relatively unstable which becomes rapidly degraded within an hour, and another considerably more stable. The decrease in labelling was in every way similar to that previously observed after the mere addition of actinomycin D to the culture medium<sup>9</sup>. It should be emphasized that the labelling remained exclusively nuclear for the whole duration of the experiment.

To study the influence of RNA synthesis inhibition on the protein synthesis of erythroblasts, actinomycin D (10  $\mu\text{g}/\text{ml}$ .) was added to a suspension of bone marrow cells. Afterwards, at intervals of 60, 120 and 180 min an aliquot of medium was aspirated and incubated for 30 min with  $^3\text{H}$ -leucine (1  $\mu\text{C}/\text{ml}$ .) and smears were prepared. Cells obtained from an actinomycin-free medium and incubated with  $^3\text{H}$ -leucine after the same intervals of time acted as controls. From Fig. 3 it is obvious that the rate of protein synthesis in erythroblasts treated with actinomycin remains similar, during the time of the experiment, to that of erythroblasts untouched by actinomycin.

The present results suggest that an RNA fraction, characterized by a high degree of metabolic activity, is synthesized in the more immature stages of the red cell series. This RNA fraction does not act as a template for the proteins which are synthesized simultaneously, since the inhibition of its synthesis, and its breakdown, do not cause a parallel decrease in the rate of protein synthesis.

The existence of an RNA fraction with such characteristics in the more immature stages of the red cell series is of interest. In fact, in the final stages of this cellular line, that is in reticulocytes, haemoglobin synthesis takes place in the presence of a stable RNA fraction<sup>6</sup>, while the synthesis of a DNA-dependent RNA must be excluded<sup>6,12</sup>. Consequently it seems probable that the information which is required for protein synthesis must have been prepared in earlier stages. On account of the presence in these early cells of an unstable RNA and because the metabolic instability observed appears to be characteristic of messenger RNA<sup>4</sup>, it seems not unreasonable to suppose that the elaboration of information is linked with the synthesis of a labile RNA messenger fraction in erythroblasts also.

## Salicylic Acid as a Metabolite of L-Tryptophan

The metabolites appearing in the urine after an oral load of L-tryptophan have been separated by paper, thin-layer and column chromatography. After ingestion of L-tryptophan (70 mg/kg body-wt.) the urine was collected at timed intervals over the next 24 h. Aliquots of the urine were examined by two-way paper chromatography (n-butanol-acetic acid-water, 12:3:5, followed by 20 per cent KCl in water), and by thin-layer chromatography on silica gel using chloroform, methanol, acetic acid (76:22:2 by volume). The metabolites were located with Ehrlich and Pauly reagents<sup>1</sup> and by fluorescence in ultra-violet light at two wave-lengths (253 and 366 mμ).

During the course of this investigation, 9 out of 23 normal individuals examined were found to excrete an unknown metabolite, which had an *R<sub>f</sub>* of 0.75 on thin-layer chromatography and which occupied a position to the right of acetyl-3-hydroxykynurenine<sup>2</sup> on two-way paper chromatography. The unknown compound could

also be separated by chromatography of the urine on a column (50 cm × 0.9 cm) of DEAE 'A-25 Sephadex' (Cl- form) which had been equilibrated with 0.2 N hydrochloric acid in 10 per cent isopropanol. The unknown substance was eluted after the passage of 40–45 ml. of the acid propanol mixture, and after acid hydrolysis was found to contain glycine. An authentic sample of salicylic acid showed identical behaviour under all these conditions.

It is well known that ingested aspirin is largely excreted as salicylic acid but apparently it has escaped notice so far that salicylic acid is excreted by many people after a load of L-tryptophan, and when the possibility of acetylsalicylic acid ingestion during the period of the experiment has been rigorously excluded.

We believe that the salicylic acid arises from L-tryptophan by bacterial action in the colon, is then absorbed, and after conjugation with glycine is excreted as salicylic acid. The colonic origin is suggested by the facts that: (1) the peak of excretion is 10–14 h after oral ingestion of the L-tryptophan, which is considerably later than the peak excretions of tryptophan metabolites of endogenous origin; (2) salicylic acid is not found in the urine of patients who are receiving neomycin; (3) the introduction of L-tryptophan directly into the colon causes a much greater excretion of salicylic acid, as compared with the oral dose.

## Methods for Detection of Enzymatic Activity after Electrophoresis on Polyacrylamide Gel in *Drosophila* Species

Our laboratory is investigating several proteins within the genus *Drosophila*. In conjunction with this work, we have developed techniques for detecting enzymatic activity following electrophoresis on polyacrylamide gel. Several other methods for demonstrating specific enzyme activity in *Drosophila* have been reported<sup>1–3</sup>; these were applied after starch-gel electrophoresis.

The methods here described have given satisfactory results for malic dehydrogenase, α-glycerophosphate dehydrogenase and non-specific esterases when used to test a number of species. *D. virilis* Pasadena strain and *D. melanogaster* Oregon-R strain have served as controls.

Polyacrylamide gels are prepared, using a modification of the method of Hubby<sup>4</sup>. Before catalysts are added the 5 per cent monomer solution is heated to 45° C. The heating allows polymerization to occur within 20 min in the presence of only 0.8 per cent ammonium persulphate (AP) and 0.13 per cent dimethylaminopropionitrile (DMAPN). The reduction in amount of AP eliminates the necessity for an equilibration period before electrophoresis. The gels are cooled during electrophoresis by a Sargent water cooler, which maintains the temperature of the gel at 9° C.

Extracts are prepared of whole adult frozen flies, 1–2 days in age. The flies are ground in five parts of 5 per cent sucrose in 0.1 M phosphate buffer, pH 6.5, and centrifuged 20 min in a Servall model 'A' centrifuge at 6,780g. A 20-μl. aliquot of the supernatant is placed in each trough of the cooled gel.

Electrophoresis is usually carried out for 90 min at 28 V/cm. The current is about 75 m.amp. At the end

of this period the gels are removed and placed in the appropriate incubation medium.

The methods for the detection of the dehydrogenases are similar to one another. For malic dehydrogenase (MDH): 0.1 M neutralized sodium malate; 20 µg/ml. phenazine methosulphate (PMS); 0.3 mg/ml. nicotine adenine dinucleotide (NAD); 0.3 mg/ml. nitro blue tetrazolium (Dajac Laboratories); in 0.1 M phosphate buffer, pH 7.4. For  $\alpha$ -glycerophosphate dehydrogenase ( $\alpha$ -GDH): 0.1 M glycerophosphate ( $\alpha$ , $\beta$ -mixture; Cal. Biochem.); 16 µg/ml. PMS; 0.15 mg/ml. NAD; 0.3 mg/ml. Nitro BT; in 0.1 M *tris* HCl buffer, pH 8.3. Gels are incubated 3–4 h at 25° C.

For the esterase assay the gel is soaked in 0.5 M boric acid (pH 4.1) for 90 min at 4° C. This procedure lowers the pH of the gel itself from 8.9 to approximately 7.0, at which pH the reaction proceeds readily. The low temperature keeps diffusion of the protein within the gel at a minimum. The gel is then rinsed rapidly in two changes of distilled water and placed in a tray containing 1 ml. 2 per cent  $\alpha$ -naphthyl acetate in acetone and 50 mg fast red TRN (*p*-chloro-*o*-toluidine diazonium salt) in 100 ml./0.1 M phosphate buffer, pH 6.5. The gel is incubated with constant agitation 3–4 h at 25° C.

All systems were tested without substrate to determine the specificity of the reaction. Bands which appeared only in the presence of the complete system were considered to represent sites of activity of the enzyme in question. The number of bands observed after staining depends on the particular species tested as well as the particular enzyme (see Fig. 1).

In *D. virilis* Pasadena, MDH is represented by a single band, whereas there are two in *D. melanogaster* Oregon-R. Both have one band of  $\alpha$ -GDH; it has the same mobility in the two species. There is an additional band present nearer the origin when the gel has been stained for MDH or  $\alpha$ -GDH. This band is not substrate specific, but seems to be present in any NAD-linked dehydrogenase system. There are ten sites of esterase activity in *virilis*, used six to

seven in *melanogaster*. A few bands have the same mobility in both species.

The methods described here are being used to obtain information on evolutionary relationships in the genus *Drosophila* and to examine genetic variation in natural populations.

This work was supported by a traineeship from the U.S. Public Health medical training grant 5T1-GM-150, National Institutes of Health genetics training grant 2G90(CO5) and by National Science Foundation grant GB-630.

### A Simple Method for measuring Ribonucleic Acid Content of Preparations of Deoxyribonucleic Acid

In recent years an increasing number of varied biological activities have been found associated with highly purified DNA. It is of some importance, in interpreting the effects of DNA on biological systems, to determine quantitatively the RNA content of such DNA preparations. Unfortunately, at the present time there is no generally accepted standard procedure to estimate small amounts of RNA in the presence of high concentrations of DNA. The orcinol method<sup>1,2</sup>, as is well known, gives falsely high RNA values because DNA itself reacts with the reagent to a limited extent. We have tested a variety of reported modifications of this orcinol procedure and have found them unsatisfactory. They have produced results indicating the presence of 5–10 per cent "RNA" in DNA preparations containing no demonstrable uracil after acid hydrolysis and paper chromatography (<3 per cent RNA). Therefore, a simple, rapid method, used successfully in this laboratory to estimate RNA content, appears to be worth reporting.

RNA is soluble but DNA is insoluble in 1 N cold perchloric acid. Ogur and Rosen<sup>3</sup> in 1950 suggested that this solubility difference could be used to extract differentially the nucleic acid from tissues. Following their methods, we incubated nucleic acid solutions for 18 h at 4° C in 1 N perchloric acid, and found all the RNA in solution. However, as much as 10 per cent of the DNA had also dissolved under these conditions of prolonged exposure of DNA to the acid. It was noted, in contrast to the earlier work with tissues, that the RNA in aqueous solution was immediately completely soluble in the cold perchloric acid and the DNA was insoluble. Therefore, prolonged incubation was unnecessary and the method was standardized as follows.

DNA is dissolved in distilled water to a concentration of approximately 0.5 mg/ml. and kept chilled at 0° C in an ice bath. Ice-cold concentrated perchloric acid is added to the DNA solution to a final concentration of 1 N. A white, turbid DNA precipitate forms and the suspension is immediately filtered three times repeatedly through the same filter paper. The tubes receiving the filtrates must be in the ice bath and the cycle of repeated filtrations should be complete within 20 min. To prevent any precipitated DNA from redissolving, it is essential that the filtrations be performed rapidly and in the cold. The final filtrate is crystal clear. The absorbance of the filtrate is determined in a Beckman DU spectrophotometer (room temperature) at 260 mµ against a blank of 1 N perchloric acid.

Yeast RNA (Schwartz Bioresearch) was analysed by this method at concentrations of 2–20 µg/ml. A

Fig. 1. Enzyme activity after polyacrylamide electrophoresis of *D. melanogaster* Oregon-R (M) and *D. virilis* Pasadena (V). (a) MDH, (b)  $\alpha$ -GDH, (c) non-specific esterase (dotted line indicates a band usually present but not shown in the photograph)

straight line running through the origin with a slope of 0.021 O.D./ $\mu$ g RNA represents our standard curve for quantitative determinations. Examination of highly purified, freshly prepared, mammalian DNA solutions<sup>4,5</sup> showed <1 per cent (0.5–0.8 per cent) RNA content by this method. Known quantities of RNA have been added to these DNA solutions and the mixtures analysed. The results were a simple summation of the expected RNA values plus the absorbances of the DNA solutions alone.

The small amount of perchloric acid-soluble material in the DNA solutions probably reflects the limited reaction of the DNA itself with the reagent rather than the true presence of RNA. This is suggested by our finding of a significant increase in the perchloric acid-soluble material when the DNA is exposed to the acid for longer periods at slightly higher temperatures. This reaction of DNA with the reagent is similar to the interference of DNA with other methods of measuring RNA. An advantage of this method, performed rapidly in the cold, is that the interference of the DNA is quantitatively so small (<1 per cent) that an accurate measurement of RNA is possible. Therefore, the finding of more than 1 per cent RNA in a DNA solution, by the procedures described here, indicates the presence of significant amounts of RNA.

This work was carried out during the tenure of an established investigatorship of the American Heart Association (J. P. S.), and was supported by grant AM-02286 from the National Institutes of Health.

### D-Tyrosine Metabolism in *Sorghum vulgare* Seedlings

It has previously been reported that sorghum seedlings incorporate carbon-14 from DL-tyrosine-2-<sup>14</sup>C into the nitrile carbon of *p*-hydroxymandelonitrile- $\beta$ -glucose<sup>1</sup>. Furthermore, it was demonstrated that <sup>14</sup>C from D-tyrosine-2-<sup>14</sup>C was not incorporated into *p*-hydroxymandelonitrile- $\beta$ -glucose<sup>1</sup>. It was also shown that a radioactive material which migrated differently from either the glucoside or tyrosine could be extracted from seedlings allowed to metabolize either DL-tyrosine-2-<sup>14</sup>C or DL-tyrosine-3-<sup>14</sup>C. Similar experiments with L-tyrosine-<sup>14</sup>C did not yield appreciable radioactive material in this portion of the chromatogram. These preliminary experiments suggested that D-tyrosine metabolism in *Sorghum vulgare* seedlings may not be affected through either a deamination or racemization as either process would lead to precursors of *p*-hydroxymandelonitrile- $\beta$ -glucose<sup>1,2</sup>.

This report records results of experiments of the metabolism of D-tyrosine in sorghum seedlings. The data suggest that D-tyrosine is metabolized by some pathway other than oxidative deamination, transamination or decarboxylation. These processes would yield *p*-hydroxyphenyl pyruvate and tyramine, respectively.

Sorghum seeds were germinated as previously described<sup>1</sup>. Seedlings, 2–3 cm high, were transferred to 15 ml. of solution in 50-ml. beakers containing 10  $\mu$ moles of D-tyrosine and 2  $\mu$ o. of D-tyrosine labelled with <sup>14</sup>C in either the carboxyl,  $\alpha$ - or  $\beta$ -carbon atoms. An additional beaker containing similar quantities of L-tyrosine and L-tyrosine-<sup>14</sup>C was used as a control. Each beaker contained 15 seedlings. The solutions were aerated for 40 h at room temperature in the light. At the end of the aeration period the shoots were separated from seeds and

Fig. 1. Chromatographic separation of metabolites of D-tyrosine and L-tyrosine obtained from 80 per cent alcoholic extracts of *Sorghum vulgare* seedlings. Figures show that carboxyl or  $\alpha$ -labelled D-tyrosine yield alcohol soluble components that are unlike the major component (*p*-hydroxymandelonitrile- $\beta$ -glucose,  $R_f$  0.8 (1)) derived from L-tyrosine

roots. The shoots were macerated and extracted with hot 80 per cent ethanol. The alcoholic extracts were chromatographed in butanol, pyridine, water (6:4:3) and the chromatograms scanned with a 4-pi scanner.

Fig. 1 shows the separation of radioactive components. This figure shows that <sup>14</sup>C from both D-tyrosine-1-<sup>14</sup>C and D-tyrosine-2-<sup>14</sup>C was incorporated into material that migrated at  $R_f$  0.15. No radioactivity from L-tyrosine-<sup>14</sup>C was incorporated into this area of the chromatograms. Chromatography of extracts from seedlings that had metabolized D-tyrosine-3-<sup>14</sup>C (not shown) gave a pattern similar to D-tyrosine-2-<sup>14</sup>C. It should be noted that chromatograms of these extracts containing  $\alpha$ - or  $\beta$ -labelled D-tyrosine also contained a radioactive area at  $R_f$  0.3 which was not found in extracts of seedlings containing carboxyl-labelled D-tyrosine. Similar experiments with tyramine-8-<sup>14</sup>C did not yield <sup>14</sup>C in the  $R_f$  0.15 or 0.30 areas of the chromatograms. This figure and other results suggest that decarboxylation occurs in the metabolic process in which D-tyrosine is converted to the material migrating at  $R_f$  0.30. In addition, the materials migrating at  $R_f$  0.15 appear to contain the propanoid carbons of tyrosine. These experiments do not indicate whether the phenyl propanoid skeleton of tyrosine has remained intact.

Table 1 shows the rate of migration of some phenolic compounds when chromatographed in butanol, pyridine, water (6:4:3). It can be seen that only *p*-hydroxyphenyl serine and 3,4-dihydroxyphenyl alanine migrate more slowly than *p*-tyrosine. The unknown radioactive compound migrating at  $R_f$  0.3 is probably neither of these compounds because it has not retained the carboxyl carbon as shown by the lack of radioactivity derived from

Table 1. RATE OF MIGRATION OF SOME *p*-HYDROXYPHENYL COMPOUNDS IN BUTANOL, PYRIDINE, WATER

Compound	$R_f$
<i>p</i> -Hydroxyphenyl serine	0.80
3,4-Dihydroxyphenyl alanine	0.80
<i>p</i> -Tyrosine	0.40
<i>m</i> -Tyrosine	0.43
<i>o</i> -Tyrosine	0.44
<i>p</i> -Hydroxymandelate	0.40
<i>N</i> -Acetyl DL-tyrosine	0.50
<i>O,N</i> -Diacetyl DL-tyrosine	0.52
Tyramine	0.55
DL-tyrosine amide	0.55
<i>p</i> -Hydroxycinnamic acid	0.70
<i>p</i> -Hydroxymandelic acid	0.75
<i>p</i> -Hydroxyphenyl acetate	0.80
<i>p</i> -Hydroxybenzaldehyde	0.90

DL-tyrosine-1- $^{14}\text{C}$  in this area of the chromatogram. The material migrating at  $R_F$  0.3 is not the decarboxylation product of either *p*-tyrosine or *p*-hydroxyphenyl pyruvic acid which migrated at  $R_F$  0.55 and 0.80, respectively, in this solvent.

Experiments with cell-free systems were carried out on extracts of seedlings. The enzyme preparation was obtained by macerating the shoots of 4-day-old seedlings in 0.1 M acetate buffer, pH 5.5, followed by centrifugation at 10,000*g*. One  $\mu\text{mole}$  of L-tyrosine per ml. was added to the supernatant solution, the pH readjusted to 5.5 and the solution held at 60° C for 5 min. The solution was rapidly cooled to 5° C, followed by centrifugation at 5,000*g* for 10 min. The supernatant solution was dialysed overnight against 100 vol. distilled water followed by adjusting the dialysed solution to 0.6 saturation with solid ammonium sulphate. The precipitate formed was collected by centrifuging at 10,000*g* for 10 min and the residue taken up in 0.1 M acetate buffer, pH 5.5. Each assay contained the material isolated from 600 mg of plant material.

Fig. 2 shows the results of incubating DL-tyrosine-2- $^{14}\text{C}$  with this enzyme preparation in the presence or absence of a boiled extract from the sorghum tissue. In the presence of boiled extracts and DL-tyrosine-2- $^{14}\text{C}$  (Fig. 2c) radioactivity was incorporated into material that migrated at  $R_F$  0.1 in the solvent system previously described. Similar experiments with L-tyrosine- $^{14}\text{C}$  gave only one radioactive peak at  $R_F$  0.4 which corresponds to the rate of migration of tyrosine.

Fig. 2. Enzymatically catalysed formation of ' $R_F$  0.1' material from DL-tyrosine-2- $^{14}\text{C}$ . A partially purified enzyme from 600 mg of plant material was incubated for 1 h in 0.07 M sodium acetate buffer pH 5.5 with  $3 \times 10^{-4}$  M DL-tyrosine-2- $^{14}\text{C}$  in the presence (Fig. 2c) or absence (Fig. 2a) of a boiled extract from *Sorghum vulgare*. An aliquot of the extract was chromatographed on Whatman number 1 paper in butanol, pyridine, water (6:4:3), followed by scanning the chromatograms for radioactivity. Fig. 2a shows the zero time control. The reaction mixture was boiled prior to adding DL-tyrosine-2- $^{14}\text{C}$ . Fig. 2c shows that in the presence of DL-tyrosine-2- $^{14}\text{C}$  and boiled extract (solid line) material migrating at  $R_F$  0.1 is formed. When DL-tyrosine-2- $^{14}\text{C}$  was replaced by L-tyrosine- $^{14}\text{C}$  (dotted line) no radioactivity was observed in this portion of the chromatogram. Fig. 2b shows the effect of omitting the boiled extract.

These experiments suggest that sorghum seedlings metabolize D-tyrosine as well as L-tyrosine, however, by different pathways. *In vivo* experiments (not shown here) have shown that the conversion of D-tyrosine to materials migrating at  $R_F$  0.15 and 0.30 is blocked if  $\text{NaN}_3$ ,  $\text{NaHAsO}_4$ ,  $\text{NaF}$  or 2,4-dinitrophenol are added to the nutrient solution containing D-tyrosine. However, methylene blue did not block the formation of these materials.

These experiments give little information as to the chemical composition of the materials derived from D-tyrosine other than to eliminate a number of possible phenolic compounds including *p*-hydroxyphenyl pyruvic acid and tyramine. Chemical and chromatographic examination of the material(s) migrating at  $R_F$  0.15 indicate that it is unstable in dilute acid and gives rise to a number of  $^{14}\text{C}$ -labelled materials when derived from D-tyrosine-2- $^{14}\text{C}$ . The rate of migration in the slightly basic solvent suggests the materials to be either more acidic or of higher molecular weight than tyrosine.

The physiological importance of D-tyrosine metabolism in *Sorghum vulgare* is not known. There appears to be little or no reversible inter-conversion of L-tyrosine to D-tyrosine, while D-tyrosine appears not to be metabolized through the usual pathways for D-amino-acids, that is, deamination or decarboxylation.

We thank Miss Margie Rausch for assistance in preparation of the figures and portions of the experimental work. *p*-Hydroxymandelic acid amide was supplied by Dr. M. D. Armstrong, Fels Research Institute, Yellow Springs, Ohio, and *p*-hydroxyphenyl serine by Dr. W. A. Bolhofer, Merck, Sharp and Dohme Research Laboratories, West Point, Pennsylvania. This work was supported by research grant C-6448 from the U.S. National Science Foundation.

### Loss of Methyl Tritium from [ $^3\text{H}$ ] Acetate in Rumen Fluid

THE availability of both [ $^{14}\text{C}$ ]- and [ $^3\text{H}$ ]-labelled compounds, together with the development and refinement of scintillation counting procedures, has encouraged the use of radioisotopes in the investigation of metabolic processes. It has generally been assumed that with carbon-14 little or no isotope effect is produced and that the labelled substrate behaves in a similar way to the non-labelled compound. With tritium, however, considerable isotope effect may occur because of the large differences in atomic weights of tritium and hydrogen<sup>1</sup>.

Constant infusions of labelled substrates into animals have been widely used to measure entry rates of these compounds<sup>2</sup>. We have applied these techniques to the measurement of production rates of volatile fatty acids in the rumen of the sheep, and in the course of the work we have found that infusion of [ $^3\text{H}$ ] acetate gave considerably higher acetate production rates than infusion of [ $^{14}\text{C}$ ] acetate; this led us to investigate the possible lability of methyl tritium of [ $2\text{-}^3\text{H}$ ] acetate in rumen fluid.

Merino ewes (4-5 years old), fitted with a permanent rumen fistula, were used in these experiments. The sheep were housed indoors in single pens and were fed hourly (75 g lucerne chaff) between the hours of 8 a.m. and 7 p.m.

The animals consumed their ration in 15–20 min and were trained to eat during infusion experiments. Small quantities of a highly radioactive mixture of [ $1\text{-}^{14}\text{C}$ ] acetate and [ $2\text{-}^3\text{H}$ ] acetate were infused into the anterior end of the rumen through the rumen fistula. Rumen samples were obtained at intervals of 30 min over a period of 240 min and the acetate and butyrate isolated by column chromatography on silicic acid using hexane-butanol<sup>8</sup>. Aliquots (10 ml.) were collected off the column; 5 ml. was titrated and 5 ml. mixed with 5 ml. xylene containing 0.01 per cent 1,4-bis-2-(5-phenyloxazolyl)-benzene (POPOP) and 0.4 per cent 2,5-diphenyloxazole (PPO). These samples were counted in a Nuclear Chicago scintillation counting system 725 using the channels ratio method for dual isotopes<sup>4</sup>.

The ratio of [ $^3\text{H}$ ] to [ $^{14}\text{C}$ ] in acetate isolated from the rumen fell with time, indicating the loss of tritium from the acetate molecules (Table 1). Radioactivity appeared in the isolated butyrate and the ratio of  $^3\text{H}$  to  $^{14}\text{C}$  in this is also shown in Table 1. Infusions of [ $2\text{-}^{14}\text{C}$ ] and [ $2\text{-}^3\text{H}$ ] acetate gave essentially similar results to infusions of [ $1\text{-}^{14}\text{C}$ ] and [ $2\text{-}^3\text{H}$ ] acetate, demonstrating that the methyl group of acetate was not exchanged as a unit. Incubation of freshly obtained rumen fluid with the acetate (mixed label) at 39.5° C and in an atmosphere of 100 per cent  $\text{CO}_2$ , resulted in a similar loss of the tritium from labelled acetate (Table 1).

Table 1. THE RATIO OF  $^3\text{H}$  TO  $^{14}\text{C}$  IN RUMEN ACIDS (ACETIC AND BUTYRIC ACIDS) AND IN BLOOD ACETATE DURING AN INFUSION OF [ $^3\text{H}$ ] AND [ $^{14}\text{C}$ ] ACETATE. RESULTS FROM INCUBATION OF THE MIXED ISOTOPE WITH RUMEN FLUID *in vitro* ARE ALSO INCLUDED (EXPERIMENT 4).

Time (min)	Experiment 1 Rumen acetate $^3\text{H} : ^{14}\text{C}$	Experiment 2 Rumen butyrate $^3\text{H} : ^{14}\text{C}$	Experiment 3 Blood acetate $^3\text{H} : ^{14}\text{C}$	Experiment 4 Rumen fluid acetate $^3\text{H} : ^{14}\text{C}$
0	3.08	—	3.82	4.01
30	3.44	2.27	3.75	3.54
60	3.25	1.76	3.70	3.40
90	3.25	2.08	3.83	3.35

240	2.70	1.84	—	—

A mixture of [ $2\text{-}^3\text{H}$ ] acetate (approximately 2  $\mu\text{Ci}/\text{ml}$ ) and [ $1\text{-}^{14}\text{C}$ ] acetate (approximately 0.5  $\mu\text{Ci}/\text{ml}$ ) was infused intraruminally (1 ml./min) (experiments 1 and 2), or intravenously (0.33 ml./min) (experiment 3). The ratio of [ $^3\text{H}$ ] to [ $^{14}\text{C}$ ] was determined in acetate and butyrate isolated from rumen contents and in acetate isolated from blood. Samples were taken at 30-min intervals throughout the infusion period in all experiments. The ratio was also determined in acetate isolated from samples obtained from rumen fluid incubated *in vitro* with a mixture of [ $2\text{-}^3\text{H}$ ] and [ $1\text{-}^{14}\text{C}$ ] acetate at 39.5° under a gas phase of 100 per cent  $\text{CO}_2$  (experiment 4).

Acetate is lost from the rumen mainly through absorption into portal blood<sup>9</sup>, but little is known of the reactions of acetate in rumen fluid. It is established that there is incorporation of acetate carbon into butyrate and *vice versa*<sup>8</sup>, but the extent of this and the recycling of acetate molecules is not well known. In work now being prepared for publication we have shown that of the butyrate produced in the rumen approximately 25 per cent came from acetate and of the acetate produced 10 per cent arose from butyrate. The cycle, acetate to butyrate and back to acetate, may be responsible for some of the loss of tritium from acetate. If, however, the tritiated acetate underwent conversion to butyrate at a reduced rate this would tend to increase the ratio of  $^3\text{H}$  to  $^{14}\text{C}$  in acetate. The labelling in butyrate shows that an appreciable amount of tritium appears in isolated butyrate and the cleavage of this molecule to acetate would tend to reduce the ratio as indicated by the following equation, in which T is used to indicate tritium:

However, the recycling of acetate molecules through the above scheme must be small as indicated by the inter-conversion percentages.

From the results obtained in this investigation it is apparent that although production rates or entry rates of

acetate in the rumen may be measured using intraruminal infusions of [ $^{14}\text{C}$ ] acetate, acetate labelled with tritium cannot be used because of the apparent lability of the tritium. That [ $^3\text{H}$ ] acetate could be used for the measurement of entry rates in the whole animal was shown by intravenous infusions of [ $^{14}\text{C}$ ] and [ $^3\text{H}$ ] acetate. There was no change in the ratio of  $^3\text{H}/^{14}\text{C}$  in acetate isolated from blood over the period of infusion (Table 1).

If the lability of hydrogen in this position is truly represented by that of the tritium then acetate may supply readily mobilized hydrogen atoms for hydrogenation reactions. At present this seems highly unlikely, but the incorporation of tritium into unsaturated fatty acids in the rumen is under investigation. Since the tritium molecule is not lost from [ $2\text{-}^3\text{H}$ ] acetate in solution in water, the exchange of isotope may be a consequence of the strongly reducing conditions of the rumen. On the other hand, the exchange may be catalysed by elements or compounds in rumen fluid.

## PHYSIOLOGY

### Effect of Glucose administered *in vivo* or *in vitro* on the Respiratory Quotient of Rat Liver Tissue after Partial Hepatectomy

AFTER partial hepatectomy, the respiratory quotient of liver tissue has been found to decrease to about 0.7, which suggests predominant utilization of lipids<sup>1</sup>. As early as in the first hours after surgery a decrease of glycogen and an increase of lipids can be observed<sup>2</sup>. In these circumstances, however, marked enhancement of lipids in liver tissue probably does not represent a manifestation of a degenerative process. The lipids increase mainly in the peripheral cells of the liver lobules, where the processes connected with liver regeneration are most conspicuous<sup>3,4</sup> and thus provide a substance which, after partial hepatectomy, is utilized by liver tissue as the main source of energy. Under normal conditions, the energy of the liver tissue in rats fed *ad libitum* with a mixed diet is obtained by combustion of glycids, which is shown by the respiratory quotient near 1 (ref. 5). We therefore wondered whether the liver tissue after partial hepatectomy, when its respiratory quotient has decreased, is able to utilize glucose for its energetic metabolism if glucose is offered in excess during the acute experiment.

The experiments were carried out using Wistar male rats aged 4–5 months, weighing 240–310 g, which were fed throughout, including the course of the experiment, *ad libitum* with the standard laboratory diet: 700 g bruised wheat, 100 g dry-milk powder, 150 g casein, 30 g crushed alfalfa hay, 15 g calcium chloride, 50 g fat (100 per cent), 7.5 g liver oil, 2.5 g sodium chloride and an amount of water sufficient to obtain a pasty consistency. The respective measurements were made in normal, non-operated rats 48 h after partial hepatectomy or simple laparotomy. Rats which had not undergone surgical intervention were included in the first experimental group;

Table 1. OXYGEN INTAKE, CARBON DIOXIDE RELEASE AND RESPIRATORY QUOTIENT OF THE LIVER TISSUE AFTER ADMINISTRATION OF GLUCOSE *in vivo* OR *in vitro* TO THE RATS WHICH HAVE UNDERGONE PARTIAL HEPATECTOMY OR SIMPLE LAPAROTOMY

Groups	Oxygen intake (mm <sup>3</sup> mg <sup>-1</sup> dry tissue per 60 min)			Carbon dioxide release (mm <sup>3</sup> mg <sup>-1</sup> dry tissue per 60 min)			Respiratory quotient

Non-operated rats	3.21 ± 0.20	—	3.80 ± 0.37	2.96 ± 0.29	—	3.44 ± 0.42	0.94 ± 0.028	—	0.89 ± 0.07
48 h after partial hepatectomy	4.83 ± 0.39	5.18 ± 0.23	4.75 ± 0.28	3.76 ± 0.61	3.83 ± 0.31	3.70 ± 0.38	0.75 ± 0.069	0.76 ± 0.06	0.79 ± 0.04
48 h after laparotomy	3.33 ± 0.25	4.09 ± 0.50	3.60 ± 0.24	2.86 ± 0.36	4.03 ± 0.06	3.52 ± 0.41	0.99 ± 0.063	1.00 ± 0.11	0.97 ± 0.11

the rats of the second group were given by gastric tube 1.25 ml. of a 40 per cent solution of glucose per 100 g body-weight 30 min before killing and withdrawal of samples; in the third experimental group glucose was added in excess to the incubation medium in the Warburg flasks to a concentration of 270 mg per cent. About 70 per cent of the liver tissue was removed, following the partial hepatectomy procedure of Higgins and Anderson<sup>4</sup>. The formation of carbon dioxide and intake of oxygen by the liver slices were measured by means of the direct method of Warburg and Negelein<sup>5,6</sup>, using standard flasks with side arms and an absorption cup according to Pardee<sup>7</sup> and Krebs<sup>8</sup>. This technique enabled us to maintain a constant pressure of gaseous carbon dioxide. The tissue was suspended in Krebs-Ringer's saline solution with lower content of sodium bicarbonate (0.35 per cent) following the method of Bellamy and Bartley<sup>9</sup>. The results were evaluated statistically by means of Student's *t*-test<sup>10</sup>.

The results are summarized in Table 1. In rats which had undergone simple laparotomy the values of oxygen intake and carbon dioxide formation by the tissue slices were found, 48 h after the surgical operation, to be approximately the same in normal rats. However, in those rats which had undergone partial hepatectomy a significantly higher oxygen intake ( $P < 0.01$ ) and only a slightly higher release of carbon dioxide were observed at the same time interval after the operation. The respiratory quotient of the liver of these rats decreased to values near 0.7 ( $P < 0.05$ ) when compared with intact rats, or those with simple laparotomy. After administration of glucose *in vivo* and after its addition in excess *in vitro*, the oxygen intake and the carbon dioxide formation by the liver slices (and thus also the values of its respiratory quotient) did not change in any of the experimental groups.

Clerici and Ciccarone<sup>11</sup> have reported a lowering of the 'Crabtree effect' in the partially 'resected' liver tissue. In normal circumstances, this phenomenon consists of inhibition of the oxygen intake in the tissue slices after the administration of glucose into an incubation medium. Clerici and Ciccarone failed, however, to explain the cause of the changes in the metabolic reactivity in the liver tissue after partial hepatectomy. Our experimental results offer a simple explanation. After partial hepatectomy the liver tissue—the metabolism of which is adapted to the predominant utilization of lipids—is not able to use glucose offered in excess *in vivo* or *in vitro* during the acute experiment. The lowering of the so-called 'Crabtree effect' would thus be associated with a decrease of the utilization of glucose. Derauche *et al.*<sup>12</sup> have directed attention to the decrease of glycolysis in regenerating liver tissue. It is not clear whether the rebuilding of metabolism in the liver tissue merely represents a manifestation of an adaptation to the lack of glucose and to the simultaneous increase of lipids in the liver tissue. Many of the facts, however, suggest that fat metabolism is of great importance for regenerating liver tissue. In our own experiments we had an opportunity to observe that retardation of fat infiltration in the liver tissue after partial hepatectomy pro-

voked by protracted infusion of glucose was associated with a decrease of the rate of regeneration<sup>13</sup>.

### Crabtree Effect and the Anaerobic Glycolysis of the Regenerating Rat Liver

In the preceding communication Šimek and Sedláček state that the Crabtree effect observed by us<sup>1</sup> in the regenerating rat liver should be due to a supposed inability of the growing tissue, the metabolism of which is adapted to predominant utilization of lipids, to use glucose *in vitro*.

We believe that such an explanation is not fully acceptable. In fact, the Crabtree effect has been demonstrated only four days after partial hepatectomy—namely, when the fatty infiltration of the liver is definitely waning after having reached a peak 1–2 days following surgery, as has been shown by many research workers<sup>2–4</sup>, and recently confirmed by one of us<sup>5</sup>.

A preferential utilization of lipids instead of carbohydrates, which is verisimilar immediately after lobectomy<sup>6</sup>, seems less likely at later stages when the weight gain and the chemical composition of the liver are almost normal. However, taking for granted that four days after surgery the regenerating liver mainly relies, for its respiratory needs, on the endogenous lipids, it is nevertheless evident that it is still able to react to any addition of glucose by a lowering of the oxygen uptake (and not of the Crabtree effect, as stated by Šimek and Sedláček in the preceding communication).

On the other hand, the 'utilization' of glucose is not a determining factor in causing the Crabtree effect, since this is exerted by sugars which are substrates for hexokinase and also by 2-deoxyglucose, a carbohydrate phosphorylated by such enzyme but not further glycolysed. Glycolysis can even be blocked by iodoacetate or bromoacetate without interference with the Crabtree effect<sup>7</sup>.

So far as we know, there is no proof that the regenerating rat liver is unable to phosphorylate glucose.

From analogy with the regenerating liver, it is worth mentioning that the inhibition of respiration by addition of glucose has also been demonstrated in some neoplastic tissues which show an active endogenous oxidation of fatty acids<sup>8</sup>.

Simec and Sedláček cite a paper by Derache *et al.*<sup>9</sup> as proof that carbohydrate metabolism, or, to be exact, anaerobic glycolysis, is decreased in the regenerating rat liver. Since one of us has investigated the metabolism of the regenerating liver many times, we wish not only to emphasize that the behaviour of the anaerobic glycolysis in such experimental conditions is still highly controversial<sup>10-12</sup> but also to underline that, according to Derache *et al.*<sup>9</sup>, the anaerobic glycolysis is not decreased but increased 2 and 48 h after surgery and remains unaltered in between, as compared with controls. Furthermore, Derache *et al.*<sup>9</sup> do not specify whether the rats are fasted or fed; in such conditions it is not possible to appraise adequately the value of glycolysis, the rate of which depends on the feeding state of the animals<sup>11</sup> and, consequently, on the glycogen storage in the liver<sup>12</sup>.

Finally, the paper by Derache *et al.*<sup>9</sup> is difficult to apprehend clearly since the lactic acid was evaluated by a method<sup>13</sup> which is suited to measuring phosphates but not lactic acid; the results are also expressed in a rather odd way, as  $\mu\text{moles}$  of lactic acid phosphorus/mg proteins/h.

## Increase of the Effect of Histamine by *E. coli* Endotoxin on the Smooth Muscle

ONE of the properties of the *Brucella abortus* and *B. melitensis* endotoxins is their ability to promote motility of the uterus muscle—this we demonstrated recently<sup>1,2</sup>. The *Brucella* endotoxins can induce a remarkable sensitivity in the isolated uterus against oxytocin<sup>1-4</sup> and histamine<sup>2,5</sup> which cannot be observed in the ileum<sup>6</sup>.

The *E. coli* endotoxin exhibits a similar effect on the smooth muscle of uterus and ileum. This communication describes the sensitizing effect of the *E. coli* endotoxin on the smooth muscle in respect of histamine.

The endotoxin of the *E. coli* strains 0 55 and 0 111 were prepared by Boivin's trichloroacetic acid method<sup>7-9</sup>.

In order to demonstrate the stimulation of the effect of histamine by *E. coli* endotoxin we began with different histamine concentrations in a scale beginning with a final concentration of  $0.5 \times 10^{-6}$  down to a concentration causing a weak contraction only. This amount of histamine was said to be 100 per cent. The contraction caused by this amount and a previous 5-min incubation of the endotoxin was compared with a histamine contraction of an equal amplitude of the histamine scale. In all

Table 1. THE INCREASE OF THE EFFECT OF HISTAMINE BY *E. coli* ENDOTOXIN ON THE ISOLATED GUINEA-PIG UTERUS

No.	% Increase	No.	% Increase	No.	% Increase
1	100	10	900	19	400
2	—	11	100	20	900
3	400	12	400	21	900
4	900	13	900	22	400
5	—	14	400	23	100
6	400	15	100	24	400
7	100	16	900	25	150
8	150	17	900		
9	900	18	400		

experiments the amount of *E. coli* endotoxin was 50 $\gamma$ . The incubation volume (Tyrode's solution) was 10 ml.

The effect of histamine on the isolated guinea-pig uterus is stimulated to the extent of 100-900 per cent after addition of *E. coli* endotoxin. Only in 2 of 25 cases was a histamine-promoting effect of the endotoxin missed (Table 1).

The *E. coli* endotoxin can be washed out from the guinea-pig uterus in the recipient with stationary contents. The histamine, having been stimulated by endotoxin, has thereafter an effect scarcely above its threshold, namely, the amplitude of the contraction becomes the same as it was previously. This is to be seen in Fig. 1. It should be pointed out that in some cases even smaller amounts of histamine causing no contraction are followed by a strong contraction after addition of endotoxin.

The *E. coli* endotoxin without any previously administered histamine has no effect on the guinea-pig uterus when applied in amounts of 50-1,000 $\gamma$  in a recipient with stationary contents. However, after we observed that rat uteri respond to a single application of *Brucella* endotoxins with a rise in amplitude and frequency and a lesser rise in tonus when using a perfused recipient<sup>3</sup>, we undertook to investigate the effect of *E. coli* endotoxin in a perfused recipient.

Independently from our investigations<sup>1,2</sup>, Wiedermann *et al.*<sup>10</sup> described a direct effect of *E. coli* endotoxin on the contractility of the guinea-pig uterus in a perfused recipient which we, as already stated, could not observe in a recipient with stationary contents. Goodno *et al.*<sup>11</sup> were unable to confirm this finding when they used rat uterus or strips of human uterus. However, Wiedermann<sup>10</sup> pointed out the importance of the method applied and of the hormonal conditions of the animals. We have shown<sup>3</sup> that uteri of rats pretreated with oestradiol react more strongly than untreated controls when examined with *Brucella*

Fig. 1. Increasing effect of 50 $\gamma$  *E. coli* endotoxin during incubation for 5 min on the effect of an amount of histamine scarcely above its threshold

endotoxin in a perfused recipient. We have also emphasized that the hormonal condition is an important factor controlling the way the *Brucella* endotoxins<sup>1</sup> are acted on.

In 1961, one of us<sup>1</sup> propounded a new abortion theory in virtue of the effect of *Brucella* endotoxins on the isolated or pregnant uteri of animals (rat, guinea-pig, rabbit), and discussed the importance of different endotoxins, particularly of *E. coli* endotoxin, to the abortion and pointed to Thomas's observations<sup>12,13</sup>. Our experiments explain the abortions induced by injections of *E. coli* endotoxins with pregnant mice<sup>14</sup>.

The effect of *E. coli* endotoxin on the isolated uterus described here confirms the suggestions that abortions in parallel with increased bacterial breakdown are caused by the uterus-motility promoting effect of the endotoxins. It explains Kass's observations<sup>14,15</sup>; he demonstrated an increase of abortion rates with an increasing number of *E. coli* bacteria in the urinary bladders of pregnant women.

The effect of endotoxins on the blood vessels is well known<sup>16,17,18</sup>. In view of our results the question is raised of whether the increase of the histamine effect on the smooth uterine muscle by endotoxins is also responsible for the effect of endotoxins on the smooth blood-vessel muscles<sup>4</sup>. This might play a part in several pathophysiological phenomena, for example, in septic shock, in the localized Schwartzmann reaction, and in all phenomena in which histamine and endotoxin are involved. Hence, we have initiated suitable experiments which will be reported later. The preliminary results show that this increase of the histamine effect by endotoxins on the smooth muscle might be a general phenomenon.

### Action of Angiotensin on Sympathetic Nerve Endings in Isolated Blood Vessels

THE recent experimental findings<sup>1,2</sup> of a diminished effect of administered-angiotensin on blood pressure after acute sympathectomy or pretreatment with reserpine have directed attention to a possible relationship between the effects of angiotensin and the sympathetic nerve system. In dogs, McCubbin and Page<sup>3</sup> described an effect of angiotensin on the sympathetic nervous system resulting in an enhanced response to agents and procedures which cause release of endogenous noradrenaline. Later, Lewis<sup>4</sup> ob-

served an angiotensin-induced release of catecholamines from the suprarenal medulla of cats. In connexion with this finding he tentatively discussed an action of angiotensin at the vascular wall by local liberation of catecholamines from the sympathetic nerve endings. The two kinds of experiments (a and b) presented here were undertaken to obtain further information on the relationship between angiotensin and the sympathetic vasomotor action.

(a) Quantitative determination of noradrenaline was carried out on large blood vessels (aorta and a. carotis) of pigs. Preliminary results had shown that the pattern of mechanical activity of these arteries was similar to that of rat aortae used in type (b) of our experiments. Each artery was cut lengthwise to yield two identical strips. One strip of each pair was then rinsed for 2 h at 37° C at a rate of 2 ml./min with Tyrode's solution, the other with the same solution containing angiotensin II ('Hypertensin', 10<sup>-6</sup> g/ml.) at the same rate and temperature. Afterwards the muscle strips were homogenized and the noradrenaline content determined by means of the fluorimetric method of Bertler, Carlsson and Rosengren<sup>5</sup>.

After exposure to angiotensin, the noradrenaline content of the strips was found to be  $0.4 \pm 0.1 \gamma/g$  ( $\pm S.E.$ ) wet weight as compared with  $0.7 \pm 0.2 \gamma/g$  in the controls.

(b) Aortae of anaesthetized adult albino rats were cut spirally. A muscle strip, 1.5 mm wide and 12 mm long, was mounted in a narrow 0.3-ml. bath and rinsed continuously at a rate of 2 ml./min. with Tyrode's solution of 37° C. For the isometric recording of contractions a variable inductive transducer (Philips PT 1200) connected to an inkwriter (Varian G 11 A) was used.

The maximum amplitude of angiotensin-induced contractions ('Hypertensin' 10<sup>-6</sup> g/ml.) declined exponentially to zero with each subsequent application. Rinsing for 10 min with noradrenaline ('Arterenol' 10<sup>-6</sup> g/ml.) gave a nearly maximum contraction which was followed by a complete relaxation after washing out the drug. Subsequent renewed application of angiotensin now produced a contraction of  $85 \pm 14$  per cent of the initial angiotensin effect. These observations suggest that the vasoconstrictor activity of angiotensin is caused by a release of noradrenaline from the stores which are known to exist at the sympathetic nerve endings in the vascular wall. Thus, angiotensin can exert no effect if the stores are depleted by repeated exposure to angiotensin to such a degree that noradrenaline can no longer be released in an amount sufficient to induce a contraction. After partial replenishment by exogenous noradrenaline, angiotensin regains its activity. We were able to show that addition of cocaine (10<sup>-3</sup> g/ml.) prevents this restoration normally observed after administration of noradrenaline while it does not influence the normal contraction caused by noradrenaline. This may conveniently be explained by the known inhibitory action of cocaine on the noradrenaline uptake by the stores<sup>6,7,8</sup>. However, cocaine does not seem to block only the uptake but seems also to inhibit to some extent the release of noradrenaline. Thus, the administration of cocaine during the initial phase of an experiment partially or completely suppressed the vasomotor reaction to angiotensin. Such an inhibitory effect of cocaine on the liberation of catecholamines has already been suggested by Bejrablya, Burn and Walker<sup>9</sup>.

Our preparations from normal animals under prolonged exposure to angiotensin began to relax about 3 min after the maximum of the contraction had been reached. In preparations from animals which were pretreated with reserpine (1 mg/kg 'Serpasil' intraperitoneally 48 and 24 h before the experiment) relaxation started about 1.5 min after reaching the maximum. The shortening of the angiotensin effect can be explained by the extensive depletion of the noradrenaline stores following reserpine pretreatment<sup>9</sup>.

In some experiments the effects of tyramine (10<sup>-6</sup> g/ml.), the indirect action of which on vascular smooth muscle is well established<sup>9</sup>, were investigated. The

responses to angiotensin and tyramine were found to be qualitatively similar although angiotensin proved to be the more effective.

It is concluded that the action of angiotensin on vascular smooth muscle is an indirect one mediated by liberation of noradrenaline from the sympathetic nerve endings in the vascular wall, but an additional direct action cannot yet be excluded. This action of angiotensin may be of importance for a better understanding of various forms of hypertension.

## PHARMACOLOGY

### Comparison of T-Wave Changes in the Dog following Intravenous Administration of Chlorpromazine and Fluphenazine

As early as 1954, flattening of the T-wave following chlorpromazine administration to anaesthetized dogs was reported by Moyer *et al.*<sup>1</sup>. Marked T-wave changes were also noted by Melville<sup>2</sup> in 1958 following the administration of chlorpromazine to dogs under similar conditions. Other investigators have noted electrocardiographic alterations in man after parenteral administration of chlorpromazine. Undesirable effects on the electrocardiogram and ballistocardiogram by chlorpromazine were observed by Eliakim *et al.*<sup>3</sup>. Kupatz<sup>4</sup> recommended that chlorpromazine should not be used to tranquilize children prior to electrocardiogram determinations because the compound induced changes in the T-wave. Minor T-wave changes in the electrocardiograms of several patients treated with chlorpromazine were noted by Moyer *et al.*<sup>1</sup>.

In the phenothiazine series, electrocardiographic changes are not restricted to chlorpromazine. In man, Graupner and Murphree<sup>5</sup> found that 67 per cent of 55 adult males given daily oral doses of 150-900 mg thioridazine showed electrocardiographic changes. In the same report, these authors indicated that T-wave changes were produced in

4 of 11 dogs following 6 mg/kg oral doses of thioridazine. Kelly *et al.*<sup>6</sup> reported that oral doses of 200 mg or more of thioridazine altered ventricular repolarization (T-wave change) in 28 adults. Two patients, given 1,500 and 3,600 mg a day, died; their terminal electrocardiogram patterns were those of heart block, alternating with episodes of ventricular tachycardia.

We have found that fluphenazine has no greater depressive effect on the T-wave than does chlorpromazine when administered intravenously to dogs at the same mg/kg dose. However, the compounds are not used therapeutically at the same dosage. In a study of 400 acutely ill schizophrenic patients<sup>7</sup>, a daily oral dose of 2 mg of fluphenazine produced improvement similar to that afforded by a 200-mg daily oral dose of either chlorpromazine or thioridazine. The much lower clinical dose suggests a wider margin of safety for fluphenazine.

Investigations in our laboratory have demonstrated similar acute toxicities for chlorpromazine and fluphenazine in three animal species<sup>8</sup>. Both compounds showed corresponding cardiovascular effects in anaesthetized and unanaesthetized dogs at similar intravenous doses. Afterwards a direct comparison of the effects of the two compounds on the amplitude of the T-wave in dogs was completed.

For this investigation lead II electrocardiograms were recorded via surface electrodes from 12 unanaesthetized dogs of either sex. Chlorpromazine hydrochloride was then given intravenously in doses of 1, 3, and 10 mg/kg to each dog on different days and electrocardiograms were recorded hourly for 6 h. Eight of these dogs that showed a chlorpromazine-induced depression of the T-wave were selected for further investigation. On any given day two dogs were tested with chlorpromazine hydrochloride and two with fluphenazine hydrochloride at a dose of 3.0 mg/kg. A week later they were crossed-over as to drug and in subsequent weeks the experiment was repeated using 0.3 mg/kg doses.

The height of the T-wave at each hourly interval after dosing was compared with the pre-dose height and was expressed as a percentage increase or decrease. A no-drug control was obtained for each dog by comparing an initial T-wave height with heights measured at six-hourly intervals thereafter, without the administration of any substance. The six percentage values for changes in T-wave height obtained for each dog at each hour were averaged and are presented in Table 1. One dog was eliminated from the calculation of the mean change in T-wave height after each regimen because of aberrant values.

The data indicate that the mean percentage change after the 0.3 mg/kg dose of fluphenazine was similar to that after no drug had been given. On the other hand, this same dose of chlorpromazine and the 3 mg/kg doses of chlorpromazine and of fluphenazine caused definite reductions in the height of the T-wave.

These results demonstrate that at the same mg/kg intravenous dose fluphenazine has no more effect on the

Table 1. MEAN PERCENTAGE CHANGE IN T-WAVE HEIGHT FOLLOWING INTRAVENOUS ADMINISTRATION OF CHLORPROMAZINE HYDROCHLORIDE AND FLUPHENAZINE HYDROCHLORIDE TO UNANAESTHETIZED DOGS

Dog No.	Sex	Weight (kg)	No-drug control	3.0 mg/kg		Weight (kg)	No-drug control	0.3 mg/kg	
				Chlorpromazine	Fluphenazine			Chlorpromazine	Fluphenazine

2302	M	8.4	-13	-16	-2	8.2	-7	0	+2
Group mean				+12	-34	-32	-7	-25	-4

Each + or - figure is the mean of values obtained at each of six hourly intervals after dosing: + = increase in T-wave height; - = decrease in T-wave height.

\* Eliminated from calculation of the group means because of aberrant response to chlorpromazine.

† Eliminated from calculation of the group means because of aberrant response to fluphenazine and as no-drug control.

T-wave than does chlorpromazine. Using either the recommended starting daily doses of 30 mg for chlorpromazine and 1 mg for fluphenazine, or the 100-fold dose ratio found in the one clinical investigation, fewer undesirable cardiovascular and electrocardiographic side-effects would be expected when fluphenazine is used.

### Inhibition of Adrenocortical Responsiveness to ACTH by Actinomycin D *In vivo*

It has been reported recently<sup>1-3</sup> that acute or chronic administration of ACTH to rats results in a marked increase in adrenal protein synthesis. This is evidenced by a rise in the DNA and RNA concentrations in the gland and an increased capacity for incorporation of <sup>14</sup>C-glycine into protein in cell-free preparations of rat adrenals. Furthermore, Farese<sup>4</sup> has suggested on the basis of studies of this type that these changes in adrenal protein synthesis are specifically concerned with the mechanisms whereby ACTH induces adrenal hypertrophy and that even the steroidogenic effect of ACTH may be mediated by an effect of this hormone on adrenal protein synthesis. In order to elucidate this problem it was decided to investigate the effect of actinomycin D on the production of corticosteroids by the adrenal cortex.

Approximately 40 male rats, hypophysectomized 24 h previously and weighing 80-100 g, were given a subcutaneous injection of normal saline (0.5 ml./100 g body-weight) or a saline solution of actinomycin D in a dose of 25 µg/0.5 ml. saline/100 g body weight. Control rats were killed 30 min later. At various time intervals the remaining animals were given an intravenous injection of ACTH (2 mu./100 g body-weight), and killed 15 min later. The adrenals were removed and weighed, and adrenal corticosterone concentrations were determined by a modification of the method of Guillemain *et al.*<sup>5</sup>. The results were expressed as µg corticosterone/100 mg adrenal tissue.

Fig. 1 shows the effect of actinomycin D on the changes in adrenal corticosterone concentration produced by the administration of ACTH. It can be seen that 24 h after actinomycin the adrenals of these animals did not respond to the injection of ACTH with an increase in the production of corticosterone ( $P < 0.05$ ) while those of the saline-injected controls responded in a normal fashion.

Actinomycin D appears to be one of the most specific and best characterized inhibitors of protein synthesis. It is said to produce its effects by blocking the DNA-directed RNA synthesis catalysed by RNA polymerase by binding at specific sites on the DNA primer<sup>6-8</sup>. The present data indicate that actinomycin can eliminate the increased synthesis of steroids in the adrenals of rats *in vivo* in response to ACTH. Ferguson<sup>9,10</sup> has shown a similar inhibition of adrenal steroid synthesis in response to ACTH or 3',5'-AMP *in vitro* using the antibiotic puromycin. This substance is believed to inhibit protein synthesis in mammalian tissue at the point of transfer of amino-acids from soluble RNA to ribosomal nucleoprotein<sup>11</sup>.

Both the *in vitro* work with puromycin and the present *in vivo* findings with actinomycin D are consistent with

Fig. 1. The effect of actinomycin D on the changes in adrenal corticosterone concentration produced by the administration of ACTH to hypophysectomized rats. Horizontal lines represent the standard errors. ■, Controls; □, ACTH 2 mu./100 g.

the idea that protein synthesis is necessary for adrenal corticosteroid responsiveness to ACTH. It is interesting to note that, under similar conditions, actinomycin will also inhibit the decrease in adrenal ascorbic acid produced by ACTH<sup>12</sup>.

There have recently been several reports on the apparent increase in protein synthesis that accompanies the effects of estrogens<sup>13</sup>, androgens<sup>14</sup>, parathyroid hormone<sup>15</sup>, thyroxine<sup>16</sup>, and other hormones. Talwar and Segal<sup>17</sup> have proposed that a common feature in the mechanism of action of a variety of 'stimulatory hormones' is the triggering of the synthesis of messenger RNA, specific for bringing about biological changes characteristic of their respective target organs. It would appear that the mechanism of action of ACTH on the adrenal cortex adds further support to this thesis.

We thank Miss Aggie Gary for her assistance. Generous gifts of actinomycin D were received from Lederle Laboratories through Dr. George Boxer and of ACTH from Armour Laboratories.

# HAEMATOLOGY

## Haemoglobin J and E in a Thai Kindred

SINCE its discovery in 1956 by Thorup *et al.*<sup>1</sup> in an American Negro woman, haemoglobin J has been identified in other ethnic groups including Gujarati Indians<sup>2,3</sup>, Indonesians<sup>4,5</sup>, French-Canadian<sup>6</sup> and Swedish-American<sup>7</sup> Caucasians, Algerians<sup>8</sup>, Chinese in Singapore<sup>9</sup>, Hakkanese Chinese in Taiwan<sup>10</sup>, and Hawaiian-Chinese-Caucasians<sup>11</sup>. This communication concerns the occurrence of haemoglobin J in a Thai family; the family is of special interest because it has haemoglobin E in addition to J.

The presence of an electrophoretically fast-moving haemoglobin in addition to normal haemoglobin A was detected in one subject among 676 presumably healthy Thai soldiers stationed at Nakhornratchasima (Korat), Thailand. Results of the haemoglobin distribution<sup>12,13</sup> and haemoglobin E distribution<sup>13</sup> in that group of subjects were reported previously. Subsequent studies indicated that the electrophoretic mobilities of the haemoglobin under various pH conditions appeared to be identical to those of a fast haemoglobin found in members of a Hakkanese Chinese family in Taiwan<sup>10</sup>. Furthermore, both the Thai and the Chinese fast-moving haemoglobins appeared to have mobilities identical with that of a sample of haemoglobin J provided by Dr. Oscar Thorup from his original patient<sup>1</sup>. In addition, a sample of the Hakkanese Chinese haemoglobin was studied electrophoretically by Dr. H. Lehmann, who identified it as J. Pending completion of structure studies on the Thai haemoglobin it can be identified as J<sub>Korat</sub>.

Subsequent investigations on blood samples from 16 other members of the Thai family by Smithies's vertical starch-gel electrophoresis procedure<sup>14</sup> at pH 9.0, with the *tris*-EDTA-borate buffer system<sup>15</sup> as used by Goldberg<sup>16</sup>, disclosed the family to comprise a mixture of individuals possessing E, A + J, A + E and E + J type haemoglobin combinations. The distribution of the haemoglobin phenotypes in the kindred is shown in Fig. 1 and representative electrophoretic patterns of the haemoglobins are illustrated in Fig. 2. The E type haemoglobin components in the present subjects were identified by comparison of their electrophoretic mobilities with those of numerous other haemoglobin E and A + E samples found in the earlier studies on the 676 Thai blood samples. In those investigations an authentic Thai blood sample with haemoglobins A + E, provided by Dr. Prawase Wasi, Siriraj Hospital, Bangkok, was used for comparison. Numerous studies have reported the presence of haemoglobin E in South-east Asia since its occurrence in Thais<sup>17</sup> was initially recognized. Our work<sup>18</sup> among the 676 Thai subjects, for example, disclosed that 39, or 5.8 per cent, of the individuals were homozygous for the haemoglobin E gene and that 246, 36.4 per cent, had haemoglo-

Fig. 2. Results of starch-gel electrophoresis<sup>14-16</sup> of haemoglobins from Thai kindred. From top downward the subjects and haemoglobin types are: 1, normal control, A; 2, II-8, A; 3, II-2, J + E; 4, III-4, A + J; 5, III-5, A + J; 6, I-2, E; 7, II-6, A + E; 8, III-3, propositus, A + J.

bins A and E. The combined incidence in the Thai sample of 42.2 per cent for the E and A + E genotypes, which is higher than those reported previously, has been confirmed in recent studies among North-eastern Thais by Wasi and NaNakorn<sup>18</sup>.

Subject III-3 was the original case with type A + J haemoglobins found in our study of Thai subjects; his 2 brothers also had the same combination. Their mother, II-8, possessed only normal A-type haemoglobin; their father, II-2, possessed genes for both J and E haemoglobins, and the J haemoglobin genes in the sons were apparently inherited from him. Subject II-3, the brother of subject II-2, also had types J and E haemoglobins; his wife, subject II-9, had normal haemoglobin A. Among the children of subjects II-3 and II-9, one daughter, III-6, had types A and J haemoglobins and 2 sons, II-7 and II-8, had types A and E.

All 5 of the living siblings in the second generation of the kindred had E haemoglobins in combination either with A or J haemoglobin. Their mother, I-2, was homozygous for the E haemoglobin gene as illustrated in Fig. 2. Their father is presumed to have had A and J haemoglobins.

The present family provides the first reported examples of haemoglobin J in Thais and also of an association within a kindred of haemoglobins E and J. Due to the high density of the gene for haemoglobin E in the Thai race as described here, it is obvious that any other abnormal haemoglobin occurring in Thais would occur rather frequently in the same kindred with haemoglobin E. Among those members of the family studied thus far, subjects II-2, II-3 and II-4 are the only examples of the E + J haemoglobin combination in one individual. In future work this family will be examined clinically and haematologically.

We thank Dr. H. Lehmann for his help in identifying one of our haemoglobin J samples, and Drs. Prawase Wasi and Oscar Thorup for their generous contributions of abnormal haemoglobin samples. We also thank the medical officers and technicians of the Royal Thai Army Medical Corps for their aid in procuring blood specimens from the Thai family. Likewise the support of Capt. R. A. Phillips, Commanding Officer of NAMRU-2, and Col. James L. Hansen, director of the U.S. Army Component of the SEATO Medical Research Laboratory, Bangkok,

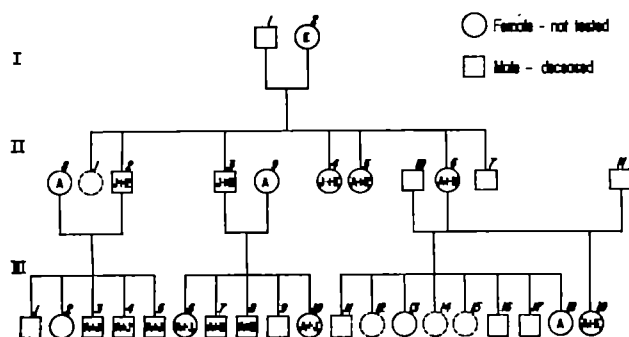

Fig. 1. Distributions of haemoglobin types E, A + E, A + J, and J + E among 3 generations of Thai kindred. Subject III-3 is the propositus.

is acknowledged. This work was supported in part by U.S. Public Law 480, Section 104(c).

### Haemoglobin E in Vietnamese

SINCE its simultaneous discovery a decade ago in an American family of mixed Spanish, Guatemalan, and Indian ancestry<sup>1</sup> and in Thais<sup>2</sup>, haemoglobin E has been found in a variety of ethnic groups a majority of which are located in the Middle East and Asia. It is particularly common among the peoples of south-east Asia where it had been found in relatively high incidence in Burmese<sup>3</sup>, Thais<sup>4-7</sup> and Cambodians<sup>8</sup>, and in lower incidences in Vietnamese<sup>9</sup>, Malaysians<sup>10,11</sup>, Indonesians<sup>12</sup>, Chinese<sup>13,14</sup> and Filipinos<sup>15</sup>. The results in this communication confirm the occurrence of haemoglobin E among Vietnamese.

Subjects for this investigation were residents of Saigon and environs. At the time of the work, during February and March 1964, they were patients in the Cho Quan Hospital, Saigon, where they had been admitted with diarrhoea during the cholera epidemic and were under treatment for dehydration. Red cells were obtained from residual heparinized blood samples collected for other diagnostic purposes and were preserved with merthiolate and by refrigeration prior to their transfer by air to the Biochemistry Department Laboratory of this Unit for analysis.

On receipt in the laboratory the red cells were washed with saline, mixed with equal volumes of distilled water, and frozen until used for electrophoretic analysis. After thawing, the samples were centrifuged and the supernatant haemolysates examined by Smithies's vertical starch-gel electrophoresis procedure<sup>16</sup>. The gel buffer employed was the *tris*-EDTA-borate buffer, pH 9.0, at the concentrations recommended by Goldberg<sup>17</sup>.

Results of the study indicate that 17, or 3.53 per cent, of the 482 subjects had A + E haemoglobins. No other abnormal haemoglobins were detected. Although no quantitative determinations were made of the relative amounts of haemoglobins A and E in the samples, haemo-

globin E was always the minor component. By inspection the E component was estimated to comprise from one-fifth to one-third of the total; in all cases it exceeded the levels to be expected for A<sub>2</sub> haemoglobin, which has the same electrophoretic mobility as E in the buffer employed.

Three cases of haemoglobin E, 2.7 per cent, were reported by Albahary *et al.*<sup>9</sup> among their 113 Vietnamese subjects. Based on the results of both investigations the incidence of the gene for haemoglobin E in the Vietnamese appears to be lower than those in Thais, Cambodians, Burmese and Malaysians, similar to those of some of the Indonesians, and higher than those of Chinese and Filipinos.

Although our results with respect to haemoglobin E in Vietnamese agree with those of Albahary *et al.*<sup>9</sup>, we were unable to confirm their finding of a slow-moving component which they called haemoglobin 'Sud-Vietnam'. No slow component other than E or A<sub>2</sub> was found among our 482 subjects.

We thank James W. Fresh, Charles Neave, Donald L. Pankratz and other members of the Cholera Treatment Team of this Research Unit, for collection and transport of the blood samples. This work was supported in part by a fund provided under U.S. Public Law 480, Section 104(c).

### Xg<sup>a</sup> Investigations of the Family of a Child with a Ring X Chromosome

THE Xg blood groups reported under this title in the issue of November 21, 1964, presented some abnormal features<sup>1</sup>. We recently had the opportunity to test the family and found the father, the mother, the daughter with the ring X chromosome, the normal daughter and the normal son all to be straightforward Xg(a+). Two examples of anti-Xg<sup>a</sup> were used.

# IMMUNOLOGY

## Immobilization Antigen in Heterozygous Clones of *Paramecium aurelia*

CLONES of *Paramecium aurelia*, heterozygous for two alleles at one of the loci specifying the immobilization antigens<sup>1</sup>, react to both parental type-specific antisera, but usually more strongly to one parental type than to the other. It is of considerable interest to determine whether these heterozygous antigens consist of one molecular species combining in varying degree the specific regions of the parental protein molecules or whether there is simply a mixture of the parental antigens. On the basis of refined serological tests, Finger and Heller<sup>2</sup> have suggested that a single hybrid molecular species is present and that the variation between clones (sometimes even derived from the same mating) is due to the formation of a hybrid combining in different ways the characters and presumably primary structure of the parental proteins.

Animals of stocks 60 and 90 of *P. aurelia* variety 1, expressing the D serotypes, were mated to produce clones of phenotype 60D/90D. About 10<sup>8</sup> of these cells were grown and the immobilization antigen extracted by methods which have been described elsewhere<sup>3</sup>. The antigen was freed from most of the contaminating protein by passing through a column of 'SE-Sephader' with a pH gradient between pH 4.2 and pH 5.6 in 0.05 M sodium acetate. This treatment produces no separation of any of the immobilization antigens which have been examined. 60 mg of antigen was then fractionated on a column of hydroxyapatite<sup>3,4</sup> at pH 6.8 at 2°–3°. Elution was with a series of sodium phosphate buffers 0.002 M, 0.010 M, 0.025 M and 0.050 M applied by a constant rate pump at 3–4 ml/h. Some 100–150 ml. of each buffer was used. Fig. 1 shows the optical density at 280 mμ. The fractions were also examined for their capacity to inhibit the immobilization reaction between both 60D animals and anti-60D serum and 90D animals and anti-90D serum (Table 1).

Fig. 1. Fractionation of 60/90D antigen on hydroxyapatite

Table 1 Inhibition of immobilization reaction		
Fraction	60D	90D
I	—	—
II	++++	—
IIIa	+++	++
IIIb	+++	++
c	+	+++

Peak I is completely inactive and is thus the remaining impurity. Peak II is eluted in the position characteristic of pure 60D antigen and gives no reaction for 90D. Pure 90D antigen would normally be eluted in the region IIIb–IIIc. Fractions IIIa and IIIc were each refractio-nated under the same conditions and were again eluted in the same region and showed the same activity pattern. No elution in any other region of the chromatogram was observed.

Thus the heterozygote antigen contains parental 60D material amounting to about 50 per cent of the total antigen. However, the remainder reacts with both anti-60D and anti-90D antisera, and consists of at least two molecular species. It was not possible to determine whether any pure 90D was present because the resolution in this region was not sufficiently good. When the original heterozygote antigen was examined serologically it appeared to contain 70–80 per cent 60D activity.

Other preparations of 60/90D antigen have given similar results.

The immobilization antigen is a protein of molecular weight 250,000 and contains two identical half-molecules held together by many disulphide bonds. These half-molecules in turn probably consist of several non-identical sub-units<sup>5</sup>. In the heterozygote the molecule might be constructed in two ways: (1) The half-molecules, made independently to give two species (60D)<sub>1</sub> and (90D)<sub>1</sub>, might then combine randomly to give three possible species—60D, 90D and (60D)<sub>1</sub>(90D)<sub>1</sub>. In the present experiment where 60D comprises 50 per cent of the total, 90D would be 10 per cent and the hybrid 40 per cent. (2) The half-molecules might be randomly assembled from the possible sub-units, and then form dimers. In the simplest case of only two sub-units, say (AB)<sub>1</sub>, the species formed would be (A<sup>60</sup>B<sup>60</sup>)<sub>2</sub>, (A<sup>60</sup>B<sup>90</sup>)<sub>2</sub>, (A<sup>90</sup>B<sup>90</sup>)<sub>2</sub>, and (A<sup>60</sup>B<sup>90</sup>)<sub>2</sub>, and the amounts in this instance 50, 10, 20 and 20 per cent. In both cases the total amount of 60D activity would be 70 per cent of the whole. Either of these simple hypotheses, particularly the second, can explain the results but, of course, it may be that the situation is more complex. Implicit in the second scheme is the suggestion that the sub-units are specified by separate genetic loci. Beale<sup>6</sup> was unable to demonstrate recombination between alleles at the D locus, but the resolving power of his methods was rather low and close linkage cannot be ruled out.

These results differ basically from those of Finger and Heller<sup>2</sup>, who suggested that only one species was formed in any clone and that the observed variation in the degree of parental type reaction was not a consequence of quantitative variation but of the exclusive formation of different hybrids in different clones. The present results suggest rather that the quantitative variation is basic and that hybrids arise in a purely random way. This quantitative variation will be examined more thoroughly. It can be considered as partial dominance at the molecular level or, in the broader sense, as an example of a very simple form of differentiation.

## PATHOLOGY

## Effect of Blood-letting on Chronic Mountain Sickness

In 1928, Monge<sup>1,2</sup> described the occurrence in the Peruvian high-altitude areas of a disease characterized by an excessive polycythaemia (greater than usual erythropoietic response to the degree of existing hypoxia) and congestive symptoms, both relieved on descent to lower altitudes. This disease, which may develop after years of residence at high levels or in natives born and living in highlands, has been called chronic mountain sickness or Monge's disease<sup>3,4</sup>. The present report describes the effects of blood-letting on the oxygen saturation, CO<sub>2</sub> pressure and pH in the arterial blood of patients with chronic mountain sickness living in Cerro de Pasco, Perú, at an altitude of 4,300 metres above sea-level.

The studies were carried out in the Cerro de Pasco Laboratory (4,300 metres) of the Instituto de Investigaciones de Altura. Three cases of chronic mountain sickness were selected on the basis of congestive symptoms, an arterial oxygen saturation (HbO<sub>2</sub> percentage) of less than 81 per cent, which is the normal figure for a similar altitude reported by Hurtado and Aste<sup>5</sup>, and a haematocrit of more than 70 per cent. In addition, they all had an arterial pCO<sub>2</sub> above 32.5 mm Hg, which is the average figure for Cerro de Pasco found by Monge *et al.*<sup>1</sup>. This last characteristic corresponds to a condition of hypoventilation recently described by Hurtado<sup>6</sup> as existing in these cases. The subjects were high-altitude natives. They slept in the laboratory the night before the experiment in order to assure basal conditions. Puncture of a brachial artery was done using a standard anaerobic technique and the blood pH was read immediately in an Astrup 'M4' micro blood pH meter. The blood pCO<sub>2</sub> was determined using the micro-equilibration technique of Astrup<sup>7</sup>. The HbO<sub>2</sub> percentage was determined in the Van Slyke apparatus. The determination of the O<sub>2</sub> capacity was carried out by tonometer equilibration at pCO<sub>2</sub> 40 mm Hg and pO<sub>2</sub> 200 mm Hg. After the arterial puncture was finished an indwelling trocar was inserted in an arm vein and a variable amount of blood was withdrawn (see Table 1). The arterial blood measurements were repeated 24 h later.

Table 1 contains the data on HbO<sub>2</sub> percentage, pCO<sub>2</sub>, pH and haematocrit of each subject before and after bleeding. It can be seen that the values after bleeding do not show important differences in cases 2 and 3. Case 1 showed a drop in HbO<sub>2</sub> percentage from 66.2 to 60.8 with no significant change in pH or pCO<sub>2</sub>. This case is interesting because the patient had, in addition to congestive symptoms, a moderate degree of heart failure. He had a drop in haematocrit from 76 to 68 in spite of a moderate bleeding of 600 ml. The three patients did not show any improvement in their symptomatology after blood was removed.

The excessive polycythaemia of chronic mountain sickness has been attributed to the increased arterial blood unsaturation secondary to hypoventilation (Hurtado)<sup>6</sup>. The purpose of the present work was to test the hypothesis of a primary excessive polycythaemia and secondary hypoventilation due to embarrassment of the cerebral circulation and activity of the respiratory centre. Our results show that 24 h after venisection the changes in pCO<sub>2</sub> were not significant and in one case there was a drop in HbO<sub>2</sub>,

percentage. These preliminary results contradict the hypothesis of primary excessive polycythaemia and secondary hypoventilation. As bleeding is often followed by a sense of well-being in cases of chronic mountain sickness, future studies are needed, testing different post-bleeding periods and studying their effect on other physiological parameters such as the elevated pulmonary arterial pressure found by Rotta *et al.*<sup>10</sup> and Peñaloza *et al.*<sup>11</sup> in these cases.

We thank Dr. George Graham for his advice.

## Experimental Tumorigenesis in the Hamster Cheek Pouch

THE cheek pouch of the Syrian hamster (*Mesocricetus auratus*) has been used in many investigations involving circulation<sup>1-3</sup>, hetero- and homo-transplantability of normal tissues and neoplasms<sup>4-7</sup>, histochemistry<sup>8,9</sup> and chemical carcinogenesis<sup>5,6,10</sup>. Salley<sup>10</sup> showed that experimental squamous cell carcinomata could be produced in the hamster's cheek pouch by painting with 9,10-dimethyl-1,2-benzanthracene. Delarue *et al.*<sup>9</sup> reported that they obtained fibrosarcomata nine months after subcutaneous implantation of paraffin pellets containing DMBA in the cheek pouch. We have reported<sup>11</sup> that a single subcutaneous injection of 3,4,9,10-dibenzpyrene at the nape of the neck induced fibrosarcomata in the hamster. The primary purpose of this investigation was to determine whether the subcutaneous tissue of the hamster's cheek pouch was as susceptible to the action of the chemical carcinogen.

One hundred and twenty female hamsters, each weighing 75-100 g, were divided among six experimental groups; the animals were lightly anaesthetized and the right cheek pouches were exteriorized. Each pouch received a single subcutaneous injection of 3,4,9,10-dibenzpyrene which had been dissolved in triolein at doses of 0.25 mg, 0.50 mg, 1.0 mg, 1.5 mg, 2.0 mg or 2.5 mg/hamster in an injection volume of 0.2 ml. for five groups. At the maximum concentration it was administered at 0.4 ml. The number of usable hamsters was reduced to 81 due to host mortality in all injected groups. They were examined weekly until death and the tumour was removed at autopsy for microscopic examination. A diet of Wayne laboratory chow was provided, with water *ad libitum*.

The number, incidence and average latency period of all observed tumours and the survival of tumour-bearing hamsters are tabulated in Table 1. Administration of 3,4,9,10-DBP at the doses used resulted in the induction of subcutaneous fibrosarcomata at the site of injection by the seventh week. The cumulative incidence was as follows: 0.25 mg/hamster, 85 per cent; 0.50 mg/hamster, 87 per cent; 1.0 mg/hamster, 100 per cent; 1.5 mg/hamster, 100 per cent; 2.0 mg/hamster, 100 per cent; and

Table 2. AVERAGE LATENCY PERIODS IN HAMSTERS RECEIVING SINGLE INJECTION OF 3,4,9,10-DIBENZOPYRENE SUBCUTANEOUSLY IN SUPRASCAPULAR AREA OR CHEEK POUCH

Agent	Dose (mg/hamster)	$\bar{X}$ Latency period (weeks) suprascapular	$\bar{X}$ Latency period (weeks) cheek pouch
3,4,9,10-DBP	2.0	9.8	14.4
	1.0	10.2	17.7
	0.5	13.0	19.5
	0.25	14.0	24.5

2.5 mg/hamster, 95 per cent. The average latency period and mean survival times were related to dosage, that is, decreasing doses of 3,4,9,10-DBP resulted in a gradual prolongation of the average latency period and mean survival time, although the tumour incidences were in close proximity for the six groups.

The average latency period of subcutaneous fibrosarcomata arising in the suprascapular area and in the cheek pouch were compared. The results shown in Table 2 demonstrated that at similar doses the average latency period was shorter when 3,4,9,10-DBP was injected in the suprascapular area.

Microscopically the 3,4,9,10-dibenzopyrene tumour (Figs. 1 and 2) was seen as a spindle cell sarcoma with areas of

pleomorphism. Multinucleated giant cells were seen in some areas and mitotic figures were present.

### Structure and Role of Cytoplasmic Ribonucleic Acid in Malignancy

X-RAY diffraction investigations<sup>1-4</sup> have indicated that RNA of normal biological material exists as an oriented helical structure with the sugar-phosphate chains forming its circumference and the hydrogen-bonded bases forming its central core. Despite the irregularity in the sequence of its bases<sup>5</sup>, RNA derives a certain degree of regularity from repetition of the O<sub>5</sub>—O—P—O—O<sub>3</sub> internucleotide linkage and from the spatial configuration of the sugar-phosphate 'backbones'.

The purpose of this communication is to propose a different structure for cytoplasmic RNA of malignant material, and to present a theory concerning its biological role in the initiation and progress of cancer.

The basic feature of the proposed structure is an overall state of irregular molecular folding consequent to loss of the three-dimensional potentiality of the molecule at multiple sites determined by the sequence of the pyrimidine bases on the polynucleotide chains.

This is proposed on the ground of my earlier observations<sup>6-10</sup> on the difference in interaction of RNAs of normal and malignant material with the basic dye acridine orange *in vivo*. Evaluated by intravital fluorescence microscopy<sup>11</sup>, cytoplasmic RNA of normal living organs, whether resting or physiologically active, exhibited no affinity to the dye cations. (The intravital fluorescence microscope used was designed by me and constructed by J. D. Möller Optical Works, Wedel-Hamburg, Germany.) On the other hand, they were bound by cytoplasmic RNA of malignant tumours in relative orientation compatible with cationic dimerization. This has been indicated by the spectral range of emission of the dimers (5470 Å–5770 Å), by their reversible disaggregation with variations of temperature and solvents and their irreversible dispersion consequent to the action of ribonuclease *in vivo*<sup>10</sup>.

Fixation of the cations to the sugar-phosphate chains was ruled out since the phosphate residues are in effective combination with the proteins, and since precipitation of the phosphate groups that may exist in a free state have not interfered with the dimerization<sup>10</sup>.

This has suggested fixation of the cations to the nucleotide plates through a competition with the hydrogen ions for the possession of the weakly acidic groups of the bases, as has been demonstrated by the reversibility of the interaction in presence of hydrogen carriers and with increase in the hydrogen-ion concentration<sup>10</sup>.

Consequently, each dimer should be located at right angles to the axis of the  $\alpha$ -helix and would comprise two

Fig. 1. Subcutaneous fibrosarcoma in hamster cheek pouch ( $\times$  c. 180)

Fig. 2. Subcutaneous fibrosarcoma in hamster cheek pouch ( $\times$  c. 330)

Fig. 1. Diagrammatic representation for the proposed disorientation of the nucleotide plates of RNA at the site of formation of acridine orange dimer

cations with an interplanar distance of 5.5 Å, which is the shortest distance for their approximation.

To account for formation of each dimer bound to cytoplasmic RNA of malignant material, I have conceived disorientation of two successive nucleotide plates in favour of an increase in the internucleotide distance demonstrated for RNA of normal material<sup>1-4</sup>. This has seemed to indicate deviation of the axis of the  $\alpha$ -helix at the binding site for each dimer (Fig. 1), with a repetition of the axial deviation that would be consistent with formation of multiple short-chain dimers.

I have found this indicative of an overall state of irregular molecular configuration such as may result from loss of the three-dimensional potentiality of the molecules at multiple sites. Recognizing that stabilization of the three-dimensional potentiality is basically a function of the primary covalent structure of the molecule, I have attributed the proposed disorientation to multifocal deformation of the  $C_5-O-P-O-C_5$  internucleotide linkage. The dispersive effect of ribonuclease on the dye complexes indicates that the enzyme has broken the continuity of the internucleotide linkage at points essentially related to the geometry of each dimer. Since ribonuclease is a highly specific phosphodiesterase which hydrolyses only secondary phosphate esters of pyrimidine nucleotide-3'-phosphate<sup>13</sup>, it is reasonable to conclude that the deformation is concerned with the  $C_5-O-P-O-C_5$  linkage, which joins a pyrimidine nucleotide with the following nucleotide in sequence. Since the deformation would most likely be a change of one or other of the bond angles, and since parallelism of the resonance systems of the cations is essential for their dimerization, I would consider that the linkage affected is pyrimidine-pyrimidine rather than pyrimidine-purine.

**Induction and biological role.** In spontaneous malignancy it is probable that the proposed structure would be a product of configurational isomerism of a normal RNA molecule, initiated by abnormal environmental fluctuations, which exaggerate the physiological minor rearrangements within the molecular structure yet permanently interfere with the reversibility to the basic configuration. A constitutional instability transmitted in the germ plasma at the molecular level could then

account for cancer susceptibility displayed by species, strains, tissues or organs.

In experimentally induced malignancy and that due to recognized aetiological agents, a multitude of mechanisms should be expected to operate. Whatever the nature of an agent or its mechanism of action, the ultimate biological effect should be interference with the three-dimensional potentiality of the RNA molecule in the manner specified.

Demonstration of the proposed structure in carcinogen-treated material as well as fully developed malignancy<sup>7,8,10</sup> has indicated its replication on the molecular level with transmission of a cancerous trait. With the extensive experimental bases for the acceptance of a nuclear hereditary system in the normal cell, this would signify a non-identical system of heredity in cancer determined by self-duplication of the proposed structure and acquisition of the folding deformity by the protein molecules. Replication of the proposed structure is conceivable in the light of the observations<sup>13,14</sup> on the self-propagating capacity of viral RNA and those on the possibility of replication of biological molecules with induced breaks in the sugar-phosphate backbone<sup>15</sup>.

The structure presumably underlies a functional disorganization at the level of the cytoplasmic organelles which would account for the faulty protein synthesis, the abnormal mitotic activity, and the disarrangement of the energy-yielding reaction which characterize malignancy.

I find the proposed structure and its suggested role compatible with earlier theories on the cytoplasmic origin of malignancy<sup>16-18</sup> and also in agreement with recent experimental observations suggestive of a qualitative change of RNA in certain tumours<sup>19</sup>.

I thank Prof. A. Ingelman Sundberg for his advice and help. I also thank Prof. M. Furuhjelm for permission to conduct the experiments in the Hormone Laboratory, Prof. H. Sobhi for his advice and Dr. R. Lundborg for his assistance in the selection of the clinical material.

## Complement-fixing Antibody to Colloid and Epithellum In Monkey Thyroiditis

HASHIMOTO's disease exhibits features not demonstrable in the autoimmune thyroiditis of guinea-pigs<sup>1</sup>, rabbits, dogs<sup>2</sup> and rats<sup>3</sup>. Diffuse lymphoid infiltration of the thyroid gland and humoral antibodies against epithelial antigens are not found in the experimental lesion<sup>4,5</sup>.

To evaluate the histological and serological characteristics of experimental primate thyroiditis, rhesus monkeys were injected with saline extract of monkey thyroid gland according to the following schedule: four monkeys received intramuscularly 2 c.c. of an emulsion composed

of equal parts of saline extract of thyroid gland (30 mg of protein/ml.) and complete Freund's adjuvant at 7-10 day intervals, and were killed 10 days after the last injection. Two monkeys received three injections and two monkeys four injections. As controls, two monkeys were injected with 'APL' (brand of human chorionic gonadotropin supplied by Ayerst Laboratories) and Freund's adjuvant, and two monkeys with 'Pergonal' (PR2016, brand of human menopausal gonadotropin supplied by Cutter Laboratories) and Freund's adjuvant. Control monkeys received four injections.

Small focal infiltrations of mononuclear cells were observed in thyroid glands of monkeys receiving three injections of thyroid emulsion. Occasionally thyroid acini were destroyed. In monkeys receiving four injections, extensive thyroid infiltrations of large mononuclear, lymphocytic and plasma cells were associated with destruction of thyroid parenchyma (Figs. 1a and b). Control monkeys exhibited rare foci of mononuclear cell infiltration.

Sera were assayed for antibody to thyroid antigens by the indirect fluorescent antibody technique. Acetone-fixed cryostat sections of normal monkey thyroid were treated with test sera followed by fluoresceinated rabbit antihuman  $\gamma$ -globulin, shown to cross-react with monkey  $\gamma$ -globulin by immunoelectrophoresis. Complement-fixation reactions were carried out by applying fresh guinea-pig serum or fresh human serum to cryostat sections of thyroid previously treated with a test serum, followed by fluoresceinated rabbit anti-guinea-pig complement or fluoresceinated rabbit anti-B<sub>1</sub>C globulin, respectively. Both reactions gave similar results, although fluorescence observed with human complement was brighter. Incubation at 5° C eliminated complement fixation (Table 1).

Sera of monkeys with severe thyroiditis contained antibodies to colloid (Fig. 2a) and epithelial antigens (Fig. 2b). Antinuclear antibodies were not observed.

Fig. 1. Thyroid gland from a monkey receiving four injections of thyroid extract-adjuvant emulsion. a, Infiltration of cells and destruction of parenchyma ( $\times 675$ ), b, mononuclear cells surrounding a partially disrupted acinus ( $\times 6190$ ).

Fig. 2. *In vitro* complement fixation by antibody from serum of a monkey with thyroiditis. a, Colloid fluorescence ( $\times 6210$ ); b, epithelial fluorescence ( $\times 6210$ ).

Table 1. IMMUNOFLOUORESCENT DEMONSTRATION OF HUMORAL ANTIBODY TO MONKEY THYROID ANTIGENS

No. of injections	Material injected	No. of monkeys	Antibodies to colloid antigen	Antibodies to epithelium	Complement-fixation reactions Colloid antibody	Epithelium antibody
3	Thyroid adjuvant emulsion	2	Weakly positive*	Negative	Negative	Negative
4	Thyroid adjuvant emulsion	2	Strongly positive	Positive	Positive	Positive
4	Hormone adjuvant emulsion	4	Negative	Negative	Negative	Negative

\* Refers to fluorescent staining observed.

Antibodies to epithelium exhibited complement-fixing properties similar to those against colloid antigens.

In human thyroiditis complement-fixing antibody to epithelium has previously been demonstrated<sup>4-6</sup> and shown to exhibit cytotoxicity in tissue culture<sup>7</sup>. The presence of complement-fixing antibodies to colloid and epithelium in sera of monkeys with thyroiditis may indicate that both these antibodies have cytotoxic potential. Although serological similarities between primate and human thyroiditis are evident, the early histological lesions resembled those in guinea-pigs, rats, rabbits and dogs. An examination of more chronic lesions in primates may, however, reveal greater morphological similarities to the human disease.

# RADIOBIOLOGY

## Evidence for Radio-Ruthenium in Milk

DURING routine counting for the determination of caesium-137 levels, an unexpected gamma-ray peak at about 0.51 MeV was observed in a number of milk samples from many different locations throughout Utah (Figs. 1 and 2). It was detected in milk produced on all dairy farms which we sampled between March 1962 and March 1963.

To determine whether the activity was actually in the milk or due to external contamination, a sample containing significant activity at 0.51 MeV was transferred into two clean one-gallon plastic bottles and re-counted. It was found that the activity at 0.51 MeV was still associated with the milk. The original bottles in which the sample was first counted showed only a small trace of the photo-peak when filled with distilled water and re-counted. No evidence of zirconium-95 was observed in the milk. Because all our samples of vegetation and soil showed appreciable zirconium-95 during this period, the absence of this nuclide suggested that the unknown emitter was in the milk and not a result of contamination with dirt during handling.

A study was conducted to determine the half-life of the unknown nuclide using this same milk sample. Counting procedures were identical to those used in routine milk

Fig. 1. Gamma-ray spectrum of the milk sample used in the half-life determination

Fig. 2. Locations of dairy farms from which milk showing a detectable photopeak at 0.51 MeV was collected

Fig. 3. Positions of sample and detector for milk counting. The 8 in.  $\times$  4 in. NaI (Tl) crystal is operated in conjunction with a 400-channel pulse height analyser

Fig. 4. Data points for the six determinations with their standard errors compared to the theoretical curves described in the text. ....,  $^{106}\text{Ru}$ ; ----,  $^{106}\text{Ru} + ^{106}\text{Ge}$ ; —,  $^{106}\text{Ru} + ^{106}\text{Tl}$

analysis (Fig. 3), but the counting time was lengthened to 400 min, and later to 800, 800 and 8,000 min for improved counting statistics in the 0.51-MeV band. The milk sample was counted 6 times during the period of March 1963–July 1964.

Calculations of relative activity at 0.51 MeV for the sample were based on a ratio of the net counts in this band (0.46–0.54 MeV) to the caesium-137 counts in the 0.66-MeV band (0.62–0.70 MeV). This ratio was selected because it would correct for any change in counting geometry between determinations and because the sample contained enough caesium-137 to be counted accurately. In all computations each energy band was corrected for the appropriate contributions from caesium-137 and potassium-40.

The ratios of the corrected net counting rate in the 0.51-MeV band to that in the 0.66 MeV (caesium-137) band were plotted on semi-log paper to show the radioactive decay of the nuclide with time. The slope of the resulting curve suggested that two emitters were present in the 0.51-MeV band (Fig. 4). These results are not incompatible with the assumption that this gamma activity was due to 865-day ruthenium-106 and 40-day ruthenium-103. A theoretical curve was constructed and plotted of combined ruthenium-103 + 106 counts expressed as a fraction of caesium-137 (Fig. 4). This was accomplished by correcting our last point back to the first determination using the physical half-period of ruthenium-106. The residual counts at the first point were assumed to be ruthenium-103 counts. Referring to commonly used lists of gamma-ray emitting nuclides, the number of possible nuclides fitting the criteria of  $\gamma$  energy and photon abundance was narrowed to seven<sup>1-4</sup>. This was done assuming that the data in the Table of Isotopes<sup>1</sup> are correct (Table 1).

Of the seven nuclides under suspicion, only three display half-lives comparable with the long-lived component of our data. Theoretical mixtures of the possible nuclides were

plotted with the curve being forced through our last point, and when possible through our first point. Then, depending on the decay of the mixture, it could be seen how compatible with the actual data line was the theoretical line. If correction for decay of rhodium-102 is made from our last determination to the date of the first determination, it changes too rapidly to lie within our standard errors. This leaves only germanium-68 and ruthenium-106 as suspects. Plotting mixtures of germanium-68 plus the short-lived component as a function of caesium-137 decay, it can readily be seen that they all lie well above the data line and the ruthenium-103 + 106 line. Of the germanium mixtures, that most compatible with our data would be germanium-68 + ruthenium-103. This is shown in Fig. 4. However, the germanium-68 + ruthenium-103 mixture still lies above the intermediate data points. The best fit to the data is a mixture of ruthenium-103 + ruthenium-106. It is logical to expect that if one isotope of ruthenium were present, the other would also be present.

Ruthenium-103 has a gamma ray at 0.498 MeV and a half-life of 40 days. Ruthenium-106 has a 365-day half-life, and its 30-sec daughter, rhodium-106, emits gamma-rays of 0.513 and 0.62 MeV. The 0.62 MeV peak is difficult to detect in the presence of large amounts of caesium-137, since it would be masked by caesium-137 gamma-rays at 0.66 MeV. If ruthenium-106 were present in this sample, some contribution would be made to the caesium-137 band from the 0.62 MeV gamma-ray of rhodium-106. The amount of this contribution can be estimated by calculating a ratio of net counts in the caesium-137 band to net counts in the 0.51 MeV band for a ruthenium-106 standard. By multiplying this ratio by the net counts for ruthenium-106 in the 0.51 MeV band of the sample, this number of counts for the six determinations can be obtained. The total net counts in the caesium-137 band attributable to the 0.62 MeV peak of ruthenium-106 ranged from 5 per cent on the first count to 2 per cent on our last count. Appropriate corrections were made. An estimated value of 7 pc. ruthenium-106/l. was calculated for the sample, for the day of collection, correcting from the last count using a 365-day half-life. The ruthenium-103 in the sample was also computed for the first count based on the calculated contribution from ruthenium-106. This value was then corrected back to the day of collection, using the 40-day half-life and gamma-ray abundances of ruthenium-103, and this was 34 pc. ruthenium-103/l. For comparison, this milk contained 54 pc. caesium-137/l.

Ruthenium is generally considered to be poorly absorbed by living systems<sup>1</sup>. However, all our hay samples, collected during 1962 and 1963, showed appreciable amounts of radio-ruthenium. Fodder heavily contaminated with relatively fresh fission products could provide a source of

ruthenium-103 and ruthenium-106 for dairy cattle, but the absence of ruthenium in milk produced in the latter part of 1963 suggests that perhaps a different chemical form of ruthenium resulting from local tests might be involved.

Further studies are needed to verify that dietary ruthenium can appear in milk and to determine the influence of the chemical form of the ruthenium. This could be accomplished by feeding various chemical forms of radio-ruthenium to cows. Analyses of the milk, excreta, blood and organs would determine the uptake, metabolism, excretion and secretion of ruthenium by dairy cattle and its significance to man.

### Intracellular Oxygen and Radiation Sensitivity

It is well known that the sensitivity of cells to ionizing radiation is commonly increased two- to three-fold by the presence of oxygen in their immediate surroundings. A great variety of plant and animal cells show this effect, but it has apparently not been demonstrated in chlorophyll-containing cells. This report describes such a demonstration and also presents evidence that oxygen generated intracellularly in photosynthesis leads to the same sensitization as oxygen from extra-cellular sources.

Vegetative chains of the freshwater green alga *Oedogonium cordiacum* (female line), collected from soil-water cultures, were irradiated in a flattened water-filled glass vessel through which gas could be continuously bubbled at about 400 ml./min. Back-diffusion of air was prevented by a narrow gas exit connected to a flow-meter. The X-ray beam (300 kVp., half-value layer 20 mm Cu, dose rate ≈ 240 rads/min) entered from one side and a light beam ('Photoflood', 150 watt, directed through a glass and water heat-filter and giving about 270 ft.-candles at the surface

of the vessel) could be passed from the other. Alternatively, the vessel could be blacked out during X-irradiation.

The condition of light or darkness, as well as equilibration with gas, was started twenty minutes before and continued during irradiation. After exposure the cells were transferred to culture medium (inorganic salt solution plus soil extract) in the dark for about 60 h and then given light from below. This treatment stimulated the transformation of the cells, without mitosis, into motile zoospores. The spores were collected on gridded slides placed on the bottoms of the vessels, as described by Horsley and Fucikovsky<sup>1</sup>, and about 240 healthy and well-attached spores in each sample were located and their positions noted. After seven to nine days' growth in culture medium at  $\approx 100$  ft.-candles (warm daylight fluorescent tubes, 16 h illumination per day) the selected cells were scored for survival. The criterion of survival was the attainment of a chain of more than twelve cells during the growth period. This criterion was chosen in preference to eight or ten cells used in other work<sup>1,2</sup> because it gave more consistent results.

There has never been any indication that the X-ray or other treatments used had any effect on the number or visible morphology of the zoospores which could be collected after stimulation, and it is assumed that the samples scored were unselected except that visibly abnormal or poorly attached spores were excluded. In some experiments a variable proportion of the selected cells failed to start growing and died at an early time: this behaviour was also unrelated to treatment. Such non-viable cells were omitted from the samples.

The effects of X-irradiation under four conditions were compared and the results are shown in Fig. 1. Unirradiated controls treated with any of the experimental gases, in the light or in darkness, gave more than 90 per cent survival, and values have been normalized to the control placed at 100 per cent. The four conditions of exposure to X-rays were: (a) air in light or in darkness with or without CO<sub>2</sub> (curve A); (b) O<sub>2</sub>-free N<sub>2</sub> in darkness or in light (curve B); (c) O<sub>2</sub>-free N<sub>2</sub> + 2 per cent CO<sub>2</sub> in the light, giving points lying near curve A; (d) O<sub>2</sub>-free N<sub>2</sub> + 2 per cent CO<sub>2</sub> in darkness, giving points lying near curve B.

The results show an increase in radiation sensitivity due to oxygen with an oxygen enhancement ratio of approxi-

mately 2.5. It can also be concluded that the increased sensitivity of cells irradiated in the presence of CO<sub>2</sub> and light is due to oxygen generated in photosynthesis. Neither light alone nor CO<sub>2</sub> alone affected sensitivity: both had to be supplied, and when this was done the sensitivity was increased to the same extent as by the presence of air dissolved in the medium.

It may further be concluded that the oxygen generated within a cell exerts its effect on radiosensitivity within that cell. Any oxygen which diffused into the surrounding water would be rapidly diluted and swept away by the stream of anoxic gas which was bubbling continuously through the irradiation vessel. This is consistent with the view that when cells show increased radiation sensitivity, due to oxygen supplied from outside, it is the oxygen which enters the cell which is important in determining sensitivity.

## BIOLOGY

### An Evaluation of Inbred Rabbit Populations by Skin Homotransplantation

ALTHOUGH the classical tissue transplantation investigations by Medawar were performed on rabbits, the lack of isogenic strains such as exist in mice and in guinea-pigs has limited the usefulness of the rabbit in experimental transplantation. Since inbred populations of rabbits are rare, we wish to report preliminary experiments carried out in such a colony.

Among the most inbred rabbit lines in the United States are those lines developed over the past thirty years by Dr. Max B. Lurie at the Henry Phipps Institute of the University of Pennsylvania. His most inbred race, the 'O' family, was started in 1938 from the Swift stock in Michigan and maintained by sibling and parent-offspring mating with occasional back-crossing necessitated by the family's low fertility<sup>1</sup>. The complexity of inheritance in this family makes difficult the precise calculation of the inbreeding coefficient.

This family is noted for its extremely low resistance to tuberculosis; during the course of the disease, the bacillus multiplies readily, and both circulating antibodies and delayed hypersensitivity to tuberculin develop slowly<sup>2</sup>. A small number of individuals of the eighteenth and nineteenth generations of this family were made available for testing their response to skin homografts. In addition, the 'AD' family, an inbred race developed in a closed colony and known to be intermediate in its resistance to tuberculosis, was tested in its tenth generation.

Skin homograft transplantation was carried out to determine the approximate degree of genetic identity present in the colony and to determine the ability of the rabbits to respond to the antigenic stimulus of skin grafts from individuals of the same family and of a foreign strain.

Under pentobarbital and ether anaesthesia, full thickness orthotopic skin grafts 12 mm in diameter were transplanted to a 5 cm  $\times$  6 cm open area overlying the panniculus carnosus of the dorsolateral thorax of the recipient. A dressing of petrolatum gauze, dry gauze, and plaster of Paris protected the graft area. In general, two homografts from a single donor and two autografts were transplanted on to the prepared bed. The open-fit method was used because it made possible more accurate estimation of prolonged graft survival times. Graft rejection was determined grossly by the onset of necrosis. This onset was characterized by changes in the appearance, texture,

Fig. 1. Survival of spores irradiated under different conditions. ●, nitrogen, oxygen-free, in light or darkness; ○, air or air + CO<sub>2</sub>, in light or darkness; △, nitrogen + CO<sub>2</sub>, oxygen-free, in darkness; ▽, nitrogen + CO<sub>2</sub>, oxygen-free, in light

and size of the graft and by the necrotic appearance of the outgrowth of epithelial cells from the graft, as described by Medawar<sup>3</sup>.

Transplantation of skin grafts in the 'O' family was designed to emphasize any genetic disparity existing between the donor and the recipient: no grafts were exchanged between siblings except from O19-38 to its non-litter-mate O19-37; a large graft dosage was used: two grafts from each donor, totalling 2.3 cm<sup>2</sup>; and, in most cases, simultaneous grafting of skin from two donors increased the dosage of any shared histocompatibility antigens.

The graft survival time was distinctly longer for grafts from donors of the 'O' family than for simultaneous grafts from the control foreign strain ('Flemish Giant') rabbits, as shown in Table 1. Excluding grafts to recipients which died with intact grafts, the average survival time of grafts from 'O' family rabbits was 30 days, compared with 12 days for grafts from the 'Flemish' rabbits. The longest survival times obtained were 58 days and 60 days.

Table 1. GRAFT SURVIVAL TIME (IN DAYS) IN THE 'O' FAMILY

Recipients	Donors' graft survival time	
O18-20	O19-10: 20 d.; O19-26: 20 d.; OH998-1 ('Flemish'): 12 d.	
O19-10	O18-20: 60 d.; O19-26: 48 d.; OH998-1: 12 d.	
O19-26	O18-20: 27 d.; O19-10: 25 d.; OH998-1: 12 d.	
O19-38	O19-37: 58 d.; O19-12: 18 d. (approximate)	
O19-18	O19-27: 18 d. (approximate)	
O19-27	O19-18: 18 d. (approximate)	
O18-22	O17-21: over 41 d. (rabbit died, no cause apparent at autopsy)	
O17-21	O18-22: over 16 d. (rabbit died, no cause apparent at autopsy)	

The 'AD' family was also tested with skin homografts. To each of five siblings were applied single grafts from the remaining four siblings and a graft from a 'Flemish Giant' rabbit. The recipients were challenged with second-set grafts six weeks later. Rabbits AD10-6 and AD10-7 and rabbits AD10-14 and AD10-15 were litter-mates; this had no observable effect on the graft survival time. However, in a separate experiment, a skin graft from rabbit AD8-30 to a non-sibling AD9-16 survived 14 days, whereas a graft from AD9-15 to its litter-mate AD9-14 survived 42 days. The latter graft survival time was the longest observed in the 'AD' family and suggested a close genetic relationship between donor and recipient.

The graft survival times for multiple simultaneous grafts in the 'AD' family siblings is shown in Table 2. The average time of sibling graft survival was 18 days for the first set and 8 days for the second set. The 'Flemish' skin grafts transplanted simultaneously with multiple 'AD' grafts survived an average of 12 days.

Table 2. GRAFT SURVIVAL TIME (IN DAYS) IN THE 'AD' FAMILY SIBLINGS (First set/second set)

Recipients	Donors' graft survival time					OH242-8 ('Flemish')
AD10-4	AD10-4	AD10-6	AD10-7	AD10-14	AD10-15	
AD10-4	—	15/6	15/6	15/6	15/6	11
AD10-6	16/8	—	18/8	15/7	16/8	11
AD10-7	28/16	19/7	—	10/8	35/7	14
AD10-14	15/7	15/7	15/7	—	15/7	12
AD10-15	*TF/20	16/11	*TF/11	15/11	—	11

\* TF: technical failure ("Second set" graft survival time was not averaged in the results for the group.)

These preliminary experiments suggest that the 'O' family and the less inbred 'AD' family are both capable of responding to the antigenic stimulus of a foreign skin graft in a normal manner. The extremely low resistance and poor immunological response to tuberculosis found in members of the 'O' family did not appear to be reflected in their response to skin homografts. The graft rejection time for recipients of both the 'O' and the 'AD' families was 12 days for a graft from a foreign ('Flemish') strain. This is slightly longer, but probably not significantly different from the average of 10.3 days (range 8-11 days) for grafts transplanted according to this method from 'New Zealand White' to 'Flemish Giant' and from 'Flemish Giant' to 'New Zealand White' rabbits.

The graft survival times for skin grafts between individuals of the 'O' family and, to a lesser extent, between

siblings of the 'AD' family suggest that progress has been made in inbreeding toward homozygosity, as determined by transplantation antigens. This is especially true of the 'O' family where the graft survival time was prolonged up to five times the value of the control grafts. However, it is evident from these studies that the 'O' rabbits cannot be considered isogenic. This is further substantiated by the fact that this family is still segregating at at least one of the five known gene loci which determine the red cell antigens, though it appears to be no longer segregating at the *a* and *b* loci which determine  $\gamma$  globulin allotypes<sup>4</sup>. The less inbred 'AD' family is still segregating at the *a*  $\gamma$ -globulin allotype locus. Other experiments have indicated that neither homozygosity for the  $\gamma$ -globulin allotypes nor for the red cell antigens alone is a sufficient condition for permanent skin homograft survival<sup>5</sup>.

Although the 'O' family shows progress toward genetic fixation, at the present time the most promising inbred strain of rabbits for homotransplantation studies appears to be the Bar Harbor line developed by Sawin, Cohen and Chai and reported by Chai<sup>6</sup>.

This investigation was aided in part by grants FR-00014 and AI-02048 from the National Institutes of Health, U.S. Public Health Service.

## Occurrence of Myogenic Hearts in Arthropods

A DIRECT demonstration of the myogenic or neurogenic origin of the heartbeat in a given animal requires morphological identification of the structures involved and proof of their pacemaker function by surgical or electrophysiological means. In small animals this is difficult to achieve, and in such cases pharmacological evidence is often used. This indirect line of argument originated with Prosser<sup>1</sup>, who showed that the hearts known at the time to be innervated myogenic were slowed by acetylcholine, that purely myogenic hearts were not affected and that neurogenic ones were accelerated. Similarly, Needham<sup>2</sup> suggested that neurogenic hearts are inhibited by ether while myogenic ones are resistant to it. Although both authors made it clear that such evidence is suggestive rather than conclusive, often in practice no other approach is feasible, and acetylcholine in particular is made to carry the full weight of the argument.

Scorpions are a case in point. Kanungo<sup>3</sup> reported that the heart of *Palamnaeus* was inhibited by acetylcholine (ACh) and insensitive to ether. This put scorpions among the small group of arthropods thought to have non-neurogenic hearts as adults. Their relatively large size permitted us to carry out a more detailed analysis of the pacemaker.

*Urodoacus* is a genus of Scorpionidae restricted to Australia. The mesosoma of our animals, and hence the tubular heart extending through it, reached a length of about 25 mm. The tergum with the heart attached was removed, inverted and the preparation perfused with

saline and ACh in varying concentrations. The inhibiting effect of ACh is dependent on concentration and, at least at lower concentrations, reversible (Fig. 1). This is the reaction attributed to an innervated myogenic heart. However, the ACh concentrations are even higher than in Kanungo's experiments, showing values characteristic of neurogenic hearts.

Ten intact animals were exposed to ether vapour and their heart rates determined. With one exception, their hearts were less resistant than the somatic musculature; even when the heart had completely stopped the legs twitched in response to puffs of air or when the table was made to vibrate. On the other hand, heart failure was a decline of amplitude only; the heart rate actually rose in all cases within a minute and before the animal became agitated—a response for which no allowance is made in Needham's scheme, but one which is in keeping with his interpretation of ether as an antagonist of ACh.

The innervation of the heart consists of the 'epicardiac nerve' of Pollee<sup>4</sup>. It runs throughout the length of the heart along the dorsal surface and is in close contact with it. Histological preparations revealed the presence of at least two types of cells: a large number of cells with small elliptical nuclei, and a smaller number (of the order of 60–100) of large cells with large round nuclei staining less strongly with both haematoxylin and borax carmine. The large cells were at first suspected of being neurones; but *in vivo* staining with methylene blue showed that it is the small cells that innervate the myocardium. Nerve fibres supply each semi-circular striated muscle bundle as well as the thin superficial layer of smooth muscle. The dorsal or cardiac nerve is therefore a cardiac ganglion.

Fig. 1. Inhibition of the heart of *Urodaeus* by acetylcholine at three concentrations. Drug added at time 0 and removed at the time indicated by dashed lines

Fig. 2. Spontaneous volleys from the detached cardiac ganglion of *Urodaeus*, recorded with external platinum electrodes. a.c. recording

The ganglion is easily detached from the heart. If this is done over a limited region, contractions stop immediately in that region, while the adjacent parts continue to beat in phase. Complex volleys (Fig. 2) can be recorded with metal hook electrodes, each volley corresponding to a systole. The complexity and variability of the discharge pattern are what one would expect from the large number of neurones involved.

Thus the heart of *Urodaeus* is clearly neurogenic, in contradiction to the pharmacological evidence. Previous claims for myogenic hearts in arthropods, so far as they rely solely on acetylcholine and ether, will have to be reconsidered in the light of this finding.

### Seasonal Changes in the Blood and Thyroid of the Grass Snake, *Natrix natrix*

CHEMICAL and physical changes in the blood during both natural hibernation and experimental hypothermia have been followed in a number of mammalian species<sup>1</sup>. Similar investigations do not appear to have been extended in any detail to the reptiles, although fish and amphibians have received some attention. The grass snake is less active during the winter, and this condition is often referred to as torpor. In preliminary investigations carried out in this laboratory during 1961, the blood from five specimens, which had entered normal winter torpor in a vivarium, was analysed in February. The ambient temperature was 7° C and some intermittent activity was observed. In July of the same year eleven specimens were available for analysis, the ambient temperature being 18° C. The results, together with comparable data on the hedgehog<sup>1</sup>, are presented in Table 1.

So far as a truly hibernating mammal is concerned quite well-defined changes are to be observed. First, there is some degree of haemoconcentration, as illustrated by the haematocrit and sodium concentration figures. Severe hypoglycaemia and leucopenia are, however, the most noticeable effects, together with a virtual doubling of the calcium:magnesium ratio, due principally to the rise in the magnesium concentration—calcium varying but little. The changes to be observed in the snake are similar in nature, but generally are of a smaller order of magnitude. Some haemoconcentration occurs, the calcium:magnesium ratio rises a little, again due chiefly to a rise in the magnesium value, but leucopenia is again severe. The glucose concentration in the blood of snakes is a highly variable quantity. Little seasonal difference is to be

	Snake		Hedgehog	
	Summer	Winter	Summer	Winter
Average body weight (g)	52.5	71.0	—	—
Haematocrit (%)	32.2	34.2	45	58
±	±1.6	±2.8		
Red blood cells (× 10 <sup>6</sup> )	0.23	1.08	8.9	9.2
±	±0.05	±0.12		
White blood cells (× 10 <sup>6</sup> )	5.4	1.56	6.0	1.6
±	±0.7	±0.13		
Glucose (mg%)	44.0	44.6	125	44
±	±8.0	±9.0		
Sodium (mM/L)	156	166	156	168
±	±3	±4.5		
Potassium (mM/L)	5.1	4.2	6.6	7.0
±	±0.36	±0.3		
Calcium (mM/L)	3.0	2.8	2.4	2.5
±	±0.16	±0.09		
Magnesium (mM/L)	1.8	2.1	1.3	2.5
±	±0.09	±0.13

±	±0.03	±0.04		

seen in the average values obtained, but the variation within the sample is enormous, being 20–60 mg per cent in winter and from 20–111 mg per cent in summer. In an endeavour to find a possible explanation for this wide variation, the seasonal changes in the histology of the thyroid gland were investigated. In mammals there is a marked change in the thyroid during the course of hibernation: the glandular epithelium of the follicles becomes flattened and there is an increase in stored colloid. Thyroids of grass snakes, killed by decapitation, were fixed in Bouin, stained in haematoxylin and eosin and cut from wax blocks at  $6\mu$ . The proportions of the principal components of the thyroid tissue were determined using the quantitative method of Uotila and Kannas<sup>2</sup>, whereby the amount of a given tissue touching parallel lines drawn on projected sections is expressed as a percentage of the total tissue in the visual field.

Data are available for a 12-months period which included two winters. Fig. 1 shows the seasonal changes in the amount of colloid and in the height of the glandular epithelium. Colloid storage is at a maximum in summer and autumn whereas in mammals it is maximal in winter. The height of epithelial cells varies markedly, being at a peak of  $15.2\mu$  in the first winter, which was mild, decreasing to a low level of  $4.5\mu$  by the following October and then increasing somewhat during the succeeding cold winter to a height of  $5.8\mu$ .

Fig. 1. Seasonal changes in thyroids of *Natrix*

In hibernating mammals the glandular epithelium is high in summer and late autumn and low in winter, the summer height being approximately double that of the winter height. It is interesting to observe that in the minnow the maintenance of animals at a low temperature does not result in an increase of cell height, nor does high temperature result in a decrease. The results obtained by Barrington and Matty<sup>3</sup> indicate that cell height in minnow increases with rise in temperature, the relationship being a direct one instead of an inverse one as is found in mammals. While there is generally good agreement that hibernation is accompanied by thyroid involution, small mammals in deep hypothermia often exhibit a very active thyroid although accompanied by minimal oxygen consumption.

In conclusion, two important factors associated with reptilian physiology must be pointed out. First, the enormous variation to be found between individuals, making comparative work extremely difficult, and, secondly, the evolutionary aspect. The typically mammalian homeostatic influence of the thyroid on metabolism is obviously yet to be developed, as witnessed by the

range of blood glucose values and the typically poikilothermic picture of the thyroid itself, although some control is already apparent. The seasonal variation in the white cell count is clearly demonstrated, as also is the increasingly narcotizing effect of the enhanced calcium: magnesium ratio.

### Delayed Implantation in an Equatorial Fruit Bat

At Kampala, Uganda (latitude  $0^{\circ} 20' N.$ ), there is an enormous roost of the fruit bat, *Eidolon helvum* Kerr. Numbers vary seasonally, with a maximum of about 250,000 during October–November.

A sample of about 50 bats was collected from this roost once a month from October 1962 until November 1964. Breeding is seasonal, births taking place only in February and March. The weight of the testes varies seasonally, reaching a peak in April–June, when they weigh 3–4 times as much as at their lowest weight. Histological examination shows that spermatozoa are most abundant when the testes are at their peak weights. The males thus exhibit a sexual cycle suggesting that mating occurs in April–June. This is confirmed by the presence of spermatozoa in the genital tracts of all adult females in April–June. Implanted embryos do not occur until October. Examination of the uteri of the adult females by cross-section and by dissection showed that during July–September unimplanted blastocysts were present. Hence there appears to be a delay of about three months between fertilization and implantation.

There appears to be no record of delayed implantation in equatorial mammals. Delayed implantation, however, does occur in mammals in temperate regions, for example, in the badger, *Meles meles* L.<sup>1</sup> Storage of spermatozoa and delayed fertilization occur in some insectivorous bats in temperate regions<sup>2</sup>. At  $0^{\circ} 20' N.$  seasonal change in day-length is trivial. Rain at Kampala occurs all the year round, with peaks during October–November and April–May. The bats feed on a large variety of both cultivated and wild fruits which do not appear to vary in abundance seasonally. The ecological significance of delayed implantation and seasonal breeding in *Eidolon helvum* therefore remains obscure.

### Growth of Excised Embryo Shoot Apices of Wheat *In vitro*

EMBRYO apices of the spring wheat cv. 'Koga II' were used in the investigation described here. The shoot apical meristem together with its three leaf primordia was excised under aseptic conditions, but in some experiments the coleoptile was also removed with the apex. The excised apices were inoculated on to the surface of 5 ml. of a semi-liquid basal medium containing the mineral

salts of Baldev<sup>1</sup>, 2 per cent sucrose and 0.3 per cent Difco 'Noble' agar in 3 in. x 1 in. soda-glass tubes and grown in the dark at 25° ± 1° C.

The aim in this investigation was to ascertain as precisely as possible the simplest metabolic requirements for sustained growth and organogenesis of the shoot apex separated from the more mature tissues lower down the axis. The growth response of excised apices is dependent on the number of leaves associated with the apex. Apices inoculated on to the foregoing medium, supplemented with 1 mg/l. gibberellic acid, showed a decrease in meristematic activity which is directly related to the number of leaves associated with the apex (Table 1). The possibility that the coleoptile may be supplying some special growth factor to the meristem cannot be ruled out; it is a well-known field observation that cereal seeds with damaged coleoptiles show decreased germinative energy.

Table 1. INCREASE IN LEAF NUMBER AND DRY WEIGHT OF EXPLANTS OF MEDIUM CONTAINING GIBBERELIC ACID (1 MG/L.) AFTER FOUR WEEKS' CULTURE

	Apex with coleoptile	Apex without coleoptile	Apex without coleoptile or leaf 1
Dry wt. (mg)	9.3	1.8	0.2
Increase leaf number	1.4	0.7	0

Provided the explant apex had three leaves, the inclusion of gibberellic acid in the medium produced a significant increase in apical activity, measured by the increase in leaf number, and this is accompanied by an increase in vigour of the explant. This supports the hypothesis of Ball that in angiosperm shoot apices the actively growing leaf primordia are involved in the supply of metabolites essential for the continued growth of the meristem.

The incorporation of indolyl-3-acetic acid in the concentration range of  $1 \times 10^{-8}$ – $8 \times 10^{-8}$  mg/l. had an increasing inhibitory effect on growth with increasing concentration. Below 0.05 mg/l. kinetin has no effect on growth but above this concentration it inhibits growth generally. When adenine was included in the medium, buds were frequently produced in a position on the opposite side of the shoot to the leaf axis but associated with the node of the leaf, generally just below the node (Fig. 1). Occasionally buds were produced both in the leaf axil and diametrically opposite. On odd occasions buds have been produced in this anomalous position on explants grown on media containing gibberellic acid.

Like most monocotyledons, with the exception of *Asparagus*<sup>2</sup>, the shoot apices of wheat are difficult to grow *in vitro*. However, the stimulation of apical activity by 1 mg/l. gibberellic acid and the decrease in the variability of the response when the acid is present suggest that this

hormone plays an important part in the regulation of growth in the apical meristem. Simpson<sup>3</sup> has shown that a gibberellin-like substance occurs in the shoots of wheat seedlings, particularly in the basal parts.

## Bud Initiation in Excised Roots of *Linaria vulgaris*

VEGETATIVE reproduction in *Linaria vulgaris* is effected by the formation of root-buds at the junction of the parent and some of the lateral roots. Up to four buds may be formed in the superficial layers of the lateral root within the cortex of the parent root<sup>1</sup> (Fig. 1), though parent and lateral root tissues are often not separately recognizable in this region (Fig. 2). Bud initiation does not occur until some secondary growth has occurred in the parent root.

Roots were excised from seedlings under aseptic conditions and cultured in a modified White's medium<sup>2</sup> containing thiamine and pyridoxine at 0.1 mg/l.; nicotinic acid at 0.5 mg/l.; and 2 per cent sucrose. In the first 3-weeks' passage, 11 of 183 roots grown in the dark, and 45 of 55 roots grown under 600 ft.-candles white fluorescent light, initiated buds at lateral root bases as in the intact plant.

Clones were obtained from those roots which had grown well in the first passage by sub-culture of lateral root apices. Not all roots gave satisfactory clones; apical growth or lateral root initiation sometimes ceased or

Fig. 1. Root-bud (B) of *Linaria vulgaris* initiated in the outer layers of the cortex of a lateral root, within the cortex of the parent root. (x c. 133)

Fig. 2. Root-bud (B) of *Linaria vulgaris* at a lateral root-base where the demarcation of parent and lateral root-bases is not visible. (x c. 67) of

Fig. 1. Buds in anomalous position on explants grown in medium containing adenine, after 4 weeks' culture. Scale in cm

Fig. 3. The relationship between number of lateral roots ( $L$ ) and number of lateral roots with associated buds ( $B$ ) in excised roots of *Linaria vulgaris* grown in a range of kinetin treatments in light and dark. Multiple points are indicated.  
 $\times$ , No kinetin;  $\bullet$ , 0.025 mg/l. kinetin;  $\blacktriangledown$ , 0.05 mg/l. kinetin;  $+$ , 0.10 mg/l. kinetin;  $\blacktriangle$ , 0.25 mg/l. kinetin.

became poor. Bud formation did not normally occur after the third 3-weeks' passage in light or dark, though after this time it sometimes occurred if a passage was prolonged beyond 4 weeks. Similar losses of the capacity to initiate buds have been reported in studies of other excised roots<sup>3,4</sup> and kinetin has been found to re-induce bud formation<sup>4</sup> or, in *Convolvulus arvensis*, to enhance bud initiation<sup>5</sup>.

Kinetin treatment, at 0.025–0.75 mg/l. in light or dark, of *Linaria* clones which had ceased bud initiation did not result in bud formation in the normal 3-weeks' passage. In longer experimental passages bud initiation occurred in kinetin and control treatments, but interpretation in terms of direct effects on bud initiation presented some difficulty since kinetin at or above 0.25 mg/l. inhibited root growth. Two modes of appraisal were used, and the results are presented of one experiment in which a dark-grown clone was used in a 6-weeks' experimental passage in light and dark, at 5 roots per treatment.

The number of buds per lateral root-base was not significantly increased by kinetin treatment but was greater in the light (Table 1). A decrease at 0.25 mg/l. is probably related to the general inhibition of root growth and lateral root initiation. The regressions of the number of lateral roots with associated buds ( $B$ ) on the total number of lateral roots ( $L$ ) were calculated as  $B = 0.41L - 1.58$  and  $B = 0.18L - 0.25$  (Fig. 3) for light- and dark-grown roots respectively (using the values from individual roots and including all kinetin treatments). Both regressions were significant at the  $P = 0.01$  probability-level. It was concluded that kinetin treatment had no effect on the rate of bud initiation relative to the rate of lateral root initiation, but that light relatively increased the rate of bud initiation.

In other experiments it was found that indolyl-3-acetic acid (IAA), gibberellic acid, adenine and adenosine, and combinations involving kinetin, IAA and adenine had no stimulatory effects on bud initiation. Changes in carbohydrate level were also ineffective.

Table 1. EFFECT OF KINETIN ON THE NUMBER OF BUDS PER LATERAL ROOT BASE IN EXCISED ROOTS OF *Linaria vulgaris*

Kinetin mg/l.	0	0.025	0.05	0.10	0.25
Buds per lateral root-base					
light	1.24	1.21	1.19	1.16	1.06
dark	1.02	1.02	1.09	1.00	—

Bud initiation at the base of lateral roots of *Linaria vulgaris* is a function of the lateral roots; so far it has not been positively affected by any external treatment except white light. Yet the number of buds per root-base is variable, and many root-bases do not have buds. Also, in the excised roots, bud initiation is variable in the sense that it decreases with passage number. It seems likely that bud initiation is dependent on some unknown factor(s) present in roots at excision but not synthesized to any great extent in the roots. The factor(s) are not likely to be related to conditions determining the onset of secondary growth since some cambial activity is present in clones more than three years old. Since experimental treatment with the usual growth substances is ineffective on bud initiation it seems that there may be some unknown system which controls bud initiation; this system may be susceptible to the influence of light.

### Genetic Recombination in a Blue-green Alga, *Cylindrospermum majus* Kuetz.

THE blue-green alga, *Cylindrospermum majus* Kuetz., forms a characteristic filament with single terminal heterocyst and sub-terminal spore at both ends of the filament. The alga was isolated on Allen and Arnon's nitrogen-free medium<sup>1</sup> in axenic cultures. At one stage of the growth cycle most of the filaments of the alga form characteristic spores, which are ellipsoidal with sculptured dark-brown exospore wall.

Five clones of the alga grown from spores were isolated on the above medium. Out of these clones, one is non-sporulating (Fig. 1a) in successive repeated cultures for the past three years. It thus appears to be a mutant which has lost a genetic marker  $S$  involved in sporulation. The non-sporulating mutant clone is therefore designated as  $S^-$ . Constant attempts to induce sporulation by a variety of methods including one of addition of culture filtrate from a sporulating clone and the parent strain has so far been unsuccessful. The remaining four clones are sporulating like the parent strain (Fig. 1,b). They are designated as  $S^+$ .

These clones, along with the parent strain, were screened for drug-resistance on media supplemented with a gradually increasing concentration of penicillin and streptomycin. A streptomycin-resistant strain (0.2  $\mu$ g/ml.)

Fig. 1. Photomicrographs of *Cylindrospermum majus* Kuetz.; a, non-sporulating clone; b, sporulating clone. (Phase contrast,  $\times 180$ )

of the non-sporulating clone was isolated by repeated subcultures on the antibiotic-supplemented medium. In a similar manner a penicillin-resistant strain (100 µg/ml.) of one of the sporulating clones was derived. Both these strains seem stable. They have been passed through a number of subcultures in the absence of their respective antibiotics without having lost their resistance.

Each of the resistant strains was tested for cross-resistance to the other antibiotic and showed no growth on antibiotic-supplemented media. They were also inoculated—separately or simultaneously—into media which contained both the antibiotics. No growth was found to have occurred in any case even after two months. However, when the two strains (designated as *S-Sm<sup>r</sup>P<sup>r</sup>* and *S-Sm<sup>r</sup>P<sup>r</sup>*) were grown together in the basal medium containing no antibiotic and transferred five times in the same medium, and then inoculated in the mixture of the two antibiotics, growth occurred in two out of 47 culture tubes. This points to a case of genetic recombination due to the chance inclusion and rare distribution of recombinants in the two culture tubes where growth had occurred in the presence of both the antibiotics. The double-resistant recombinant also formed spores at low frequency. It has been passed five times in antibiotic-free medium without loss of resistance and spore character. It is highly probable that the recombinant strain (designated as *S-Sm<sup>r</sup>P<sup>r</sup>*) is formed by the transfer of the genetic marker *Sm<sup>r</sup>* of the non-sporulating clone to the sporulating clone showing penicillin resistance. These results seem to indicate the occurrence of sexual or parasexual phenomena in the blue-green alga, *Cylindrospermum majus* Kuetz.

The only other previously reported case of an apparent genetic recombination in a blue-green alga is that of *Anacystis nidulans* by Kumar<sup>2</sup>, who found it impossible to grow clones of this alga.

### Chloramphenicol Inhibition of the Growth of Green Algae

VÁZQUEZ<sup>1</sup> has recently stated that D-threo-chloramphenicol does not inhibit the growth of protozoa (with the exception of *Tetrahymena pyriformis*) and plants.

Tamiya *et al.*<sup>2</sup> have given an account of the effect of chloramphenicol on the green alga *Chlorella ellipsoidea*, and shown that at the relatively high concentration of 323 µg/ml. the rate of growth was decreased after a lag period. At ten times this concentration, growth was virtually inhibited, but at 32.3 µg/ml. no effect was observed. The reduction in the growth rate was accompanied by a decrease in the size of the cells. *Chlorella* therefore appears to be a more resistant organism to chloramphenicol than the bacteria, but still shows similar effects.

Kumar<sup>3</sup> has found that with the blue-green alga *Anacystis nidulans*, between 1–6 µg/ml. the growth rate is unaffected, but there is an increasing lag period with increase in concentration. At 8 and 10 µg/ml. no growth was observed after twelve days.

It may also be observed that the report concerning *Tetrahymena*<sup>4</sup> is somewhat ambiguous. It is stated that "growth was considerably delayed or completely arrested at 25–150 µg/ml.". This may be taken to mean that there was a lag period before growth was commenced, but it does not specifically state that the growth rate itself was affected.

I have recently carried out some experiments on the effect of D-threo-chloramphenicol on the growth and metabolism of *Scenedesmus quadricauda*, a green alga. Here,

Fig. 1. Effect of D-threo-chloramphenicol concentration on the growth rate of *Scenedesmus quadricauda*. Control growth rate = 0.59. Correlation coefficient = 0.90; significant at  $P = 0.001$ . Growth rates are the coefficients  $b$  in the equation  $\log N = a + bt$ , where  $N$  = number of colony units (of four cells) per unit volume, and  $t$  is the time in days. The equation is calculated for the period of unrestricted growth only.

increasing the chloramphenicol concentration over the range 0.1–200 µg/ml. results in a progressive reduction in the growth rate (Fig. 1). This is accompanied by an increase in the lag period before unrestricted growth commences.

We have, therefore, two cases of the growth of green algae being affected by D-threo-chloramphenicol, though the levels which are effective differ considerably in the two organisms. *Scenedesmus* has more in common with the chloramphenicol-sensitive bacteria in this respect than with *Chlorella*.

### MICROBIOLOGY

#### Isoenzymes of Lactate-dehydrogenase in Micro-organisms

It is generally accepted that lactate-dehydrogenase (LDH) exists in more than one molecular species. LDH isoenzymes have been separated by (among other methods) using their eventual heat stability at 58° C (ref. 1). It has been shown that the LDH fraction prominent in heart muscle is more stable to heat than other fractions from, for example, liver tissue<sup>2</sup>. There is good correlation between this heat-stable isoenzyme and the fastest moving, anodal LDH I (nomenclature of Wieme<sup>3</sup>) in electrophoresis.

In the present investigation, we examined suspensions of *Staphylococcus pyog.*, var. *aureus* (1 ml. containing approximately 10<sup>8</sup> bacterial cells, as measured by turbidity) by the method of King<sup>4</sup> for LDH activity. Aliquots of the suspension were simultaneously exposed to 58° ± 0.2° C for 60 min in a water-bath. Twenty-four samples were examined, all determinations being made in duplicate. After heating, the LDH activity of the samples decreased by 83 per cent ( $s_x \pm 15.9$ ) with very good reproducibility.

In a second experiment, we examined strains of *Staphylococcus pyog.*, var. *aureus*, resistant to a variety of antibiotics (penicillin, streptomycin, chloromycetin, tetracycline). After exposure to 58° C, practically no LDH

activity could be shown. We conclude that *Staphylococcus* strains contain at least two LDH isoenzymes, the greater part being of a heat-labile type, similar to human 'liver' LDH (or the isoenzyme derived from malignant cells), typical of metabolism with anaerobic glycolysis. Strains of *Staphylococcus*, resistant to various antibiotics, contain less or none of the heat-stable isoenzyme. The possibility of prevalent activity in the LDH 3 zone (embryonic type\*) cannot be ruled out by the method used, and requires further attention.

It can be assumed that the isoenzyme pattern, generated in bacterial cells, is a result of differential gene formation.

## VIROLOGY

### Antiviral Activity of *p*-Nitrobenzylphosphonic Acid

*p*-NITROBENZYLPHOSPHONIC ACID (I), first prepared by

Litthauer<sup>1</sup> in 1889, has attracted little attention from biologists or biochemists. In a recent investigation<sup>2</sup> this compound was found to inhibit the activity of intestinal alkaline phosphatase. In continuation of our programme of work on phosphonic acids in various biological systems<sup>3-4</sup> we have investigated the effect of *p*-nitrobenzylphosphonic acid (*p*-NBP) on the propagation of encephalomyocarditis virus (EMC) *in vitro* and *in vivo* and found it to possess antiviral activity.

The source of EMC virus for our experiments was a 10 per cent suspension of infected mouse brain in broth which was stored at  $-15^\circ\text{C}$ . Mouse embryo tissue cultures used in this study were grown in a medium containing 10 per cent bovine serum, 0.5 per cent lactalbumin hydrolysate, Hanks's solution and standard amounts of penicillin and streptomycin. The infected cultures were maintained in Eagle's medium supplemented with 2 per cent of horse serum.

The titration of virus was performed according to the method of Tytell and Neuman<sup>5</sup>, in a modification adapted for polyoma and EMC viruses in mouse embryo tissue cultures<sup>6</sup>. The cultures, about  $4 \times 10^4$  cells/2 ml. in wide round-bottomed serological tubes, were infected with

Fig. 1. Relation of *p*-NBP concentration to inhibition of EMC virus in mouse embryo cell cultures. All cultures (about  $6 \times 10^4$  cells/3 ml.) were infected with 0.8 ml. EMC virus ( $3 \times 10^6$  P.F.U./ml.). After 2 h adsorption the maintenance medium (3 ml. per culture) and indicated amounts of *p*-NBP were added. The yield of virus, with and without *p*-NBP, was determined 20 h after infection.

virus and shaken mechanically for 1-2 h at room temperature. The cultures were then overlaid with Eagle's medium containing 1 per cent methylcellulose (British Celanese, Ltd.) and 2 per cent horse serum. After incubation for 24 or 48 h at  $37^\circ\text{C}$ , 0.1 ml. of a 0.1 per cent solution of neutral red was added to the overlay and the plaques were counted after further incubation for 3 h at  $37^\circ\text{C}$ .

The inhibition of the production of virus by varying concentrations of *p*-NBP is shown in Fig. 1.

At a concentration of  $1 \times 10^{-4}$  M of *p*-NBP 90 per cent reduction of plaque number was obtained and further increase of concentration had no additional effect. As much as a 99 per cent reduction in the number of plaques was observed when the effect of *p*-NBP was evaluated after incubation for 48 h. It is conceivable that in this case several consecutive cycles of virus replication were inhibited.

The cytopathogenic effect of mouse embryo cultures infected with EMC virus and treated with *p*-NBP was delayed and partially diminished.

Some information on the mechanism of action of *p*-NBP can be gained from the experiment presented in Fig. 2.

It appears that *p*-NBP inhibits the production of virus only when added to the cultures not later than 3 h after infection with EMC virus. The yield of virus in cultures treated with *p*-NBP 4-5 h after infection was only slightly reduced. Preincubation of the cultures with *p*-NBP for 24 h before infection did not affect the degree of inhibition.

In view of the known fact that the formation of EMC virus particles requires 3-4 h<sup>7</sup>, it may be assumed that *p*-NBP is active throughout the whole of the latent period of infection.

*p*-NBP did not inactivate the virus after 24 h contact at  $4^\circ\text{C}$ . Also the adsorption of virus to the cells was not

§ Pool from 3 mice.

Fig. 2. Effect of time of addition of *p*-NBP on the yield of EMC virus in mouse embryo cell cultures. Tissue cultures (about  $4 \times 10^6$  cells/2 ml.) were infected with 0.2 ml. EMC virus ( $1 \times 10^6$  p.f.u./ml.) for 1 h at zero time. The unadsorbed virus was removed from the cultures by washing prior to the addition of the maintenance medium. At intervals *p*-NBP was added directly to the medium. The yield of virus was measured 20 h after infection.

affected by *p*-NBP. Even when EMC virus was added to the cells together with *p*-NBP and after 1 h the inhibitor was removed by repeated washing the production of virus was not inhibited.

*p*-NBP in concentration ten times higher than those inhibiting virus multiplication did not cause any visible damage of tissue cultures observed for 1 week. Another indication of the low toxicity of *p*-NBP was obtained from an examination of its effect on respiration and aerobic glycolysis of chopped mouse embryo tissues. It was found that *p*-NBP does not affect the consumption of oxygen or production of lactic acid of tissues suspended in Krebs-Ringer solution with 0.2 per cent of glucose for 3 h. However, a slight inhibition of oxygen uptake and increase of glycolysis were observed after 4–5 h. *p*-NBP in a concentration of  $10^{-4}$  M reduced by 40 per cent the activity of alkaline phosphatase in mouse embryo homogenate. The respiration was measured manometrically<sup>8</sup>. Lactic acid was determined by the method of Barker and Summerson<sup>9</sup> and the activity of alkaline phosphatase was estimated according to King<sup>10</sup>.

In the experiments carried out *in vivo*, albino Porton mice weighing 12–16 g were used. Groups of mice were injected intraperitoneally with 0.5 ml. virus and 0.5 ml. 0.1 M solution of *p*-NBP (sodium salt, pH 7.4). This dose of *p*-NBP was not toxic to mice. The control mice received 0.5 ml. virus and 0.5 ml. physiological salt solution.

Antiviral effect of *p*-NBP was estimated by comparison of cumulative mortality (Table 2) and of the amounts of virus in blood and brain (Table 1) in groups of mice treated with *p*-NBP and untreated.

Table 2. EFFECT OF *p*-NBP ON INFECTION OF MICE WITH EMC VIRUS

Exp. No.	Inoculum* (p.f.u./1 ml.)†	Time after infection (days)	Mortality	
			+ <i>p</i> -NBP‡ dead/inoculated	Control dead/inoculated
1	$3 \times 10^6$	4	0/5	1/5
		5	0/5	3/5
		6	0/5	4/5
		7	0/4	4/5
		10	0/4	4/5
2	$1 \times 10^6$	4	1/15	0/10
		5	3/15	2/10
		6	8/15	6/10
		8	11/15	9/10
		10	12/15	9/10

\* 0.5 ml. intraperitoneally.

† *p*-NBP administered together with virus only once intraperitoneally 0.5 ml. 0.1 M sodium salt, pH 7.4.

‡ Plaque-forming units.

It appears that a single injection of *p*-NBP has some protective action against death of mice caused by infection with a small dose of EMC virus given intraperitoneally. However, the protective effect was much smaller with larger doses of virus. Striking evidence of the effect of *p*-NBP on the course of infection was obtained when the

amounts of virus in blood and brain were measured. In the group of mice infected with a small dose of virus and treated with *p*-NBP the viraemia was reduced and the penetration of virus into the brain was blocked.

It is our hope that *p*-nitrobenzylphosphonic acid and related compounds will prove to be new selective antiviral chemicals.

We thank Dr. A. C. Allison and Prof. T. Baranowski for their advice, and Mrs. M. Albin for assistance.

## GENETICS

### Synthesis of Ribonucleic Acid by the X-Chromosomes of *Drosophila melanogaster* and the Problem of Dosage Compensation

INVESTIGATIONS of the expression of various sex-linked genes in *Drosophila* have shown that for most of them their phenotypic manifestation is identical in male and female. Stern<sup>1</sup>, Muller<sup>2</sup> and later Muller *et al.*<sup>3</sup> by use of mutations such as bobbed and apricot in various doses showed that the identity and equality of genic expression between the two sexes are not associated, *a priori*, with the development of sex, but rather involves a system of genes, plus and minus modifiers, which regardless of sex tends to repress the action of extra doses of sex-linked genes. Muller proposed the name 'dosage compensation' for this effect and concluded that for each sex-linked gene there is a set of 'compensator genes'.

Dosage compensation has been a subject of modern genetic research in *Drosophila*<sup>4</sup> and also in mammals<sup>5–7</sup>, but the cytochemical examination of the mechanism of dosage compensation has been initiated only recently by Rudkin *et al.*<sup>8</sup>.

It has long been known that the single X-chromosome in the male salivary gland is almost as wide as the autosomes of the same nucleus, as are the two paired X's in the female salivary gland. Dobzhansky clearly established this fact in the examination of salivary glands of *F*<sub>1</sub> hybrids from the cross of *Drosophila inularis* × *Drosophila tropicalis*<sup>10</sup>. Feulgen as well as ultra-violet absorption spectrophotometry shows that the single X in the male, in spite of its being as thick as the two X's in the female, contains an amount of DNA equal to a 'haploid' X in the female<sup>9,11</sup>.

It therefore seems pertinent to ask two questions at this stage: First, if what is true for individual genes on Muller's theory of dosage compensation is also true for

the whole sex chromosome, at what level of genic action does the mechanism of compensation work? To be more specific, with what stage of information transfer do the compensator genes interfere? The second question is, what underlies the cytological behaviour of the X-chromosome in the male (1X2A) salivary gland. Is it part of the mechanism of dosage compensation at the molecular level?

Experiments were designed to find out whether RNA synthesis by the X-chromosomes of male and female salivary glands operates at recognizably different levels, and if so, whether it is possible to evaluate the results in terms of a repressing effect in females or an enhancing effect in males.

For this purpose, short-pulse labelling with tritiated uridine was used. The dissected salivary glands from the third instar larvae of wild-type *Drosophila melanogaster* ('Oregon R') were incubated in tritiated uridine (2  $\mu$ .) in 10  $\mu$ l. of *Drosophila* Ringer for 5 min. The usual procedure of staining, squashing and covering with stripping film (Kodak 'AR 10') was followed. The slides were exposed for 14-17 days. After development, fixation and washing, the slides were again stained in buffered Giemsa after Schmid<sup>12</sup>, dried and mounted with 'Euparal'. Grains on cytoplasm-free chromosomes were counted with an oil immersion objective at a magnification of approximately 1,280 times. Timed larvae were used in all experiments so that only chromosomes with similar puffing patterns were compared.

The following observations were made: (1) Grains were counted on single male- and paired female-X-chromosomes (tip to 3B and whole X). The autosome 3L was used as standard. Grains on the segments 61 and tip-68B of 3L were counted and the ratios of the grains on part (tip-3B) and whole X to those on the two segments of 3L were used for comparison of the values in the two sexes. (2) Grains were counted over unpaired X-chromosomes of female, and unpaired 3L autosomes of male and female nuclei. These served as controls to check the effect of physical factors such as stretching, flattening and the geometric configuration of the chromosomes. Grain distribution along various unpaired segments of X's as well as autosomes was recorded. (3) A comparison has also been made of the grain distribution on an unpaired single X and paired double X's in the same nucleus. The 3N nuclei from the triploid stock  $y^{sc} w_1 sc = FM_4 (sc^1 Y); cr/cr/cr$  formed the material for this purpose. The triploid stock was prepared by Dr. Justin Frost, and was made available to us from Dr. C. Stern's laboratory.

Table 1 gives the means of the ratios of: (a) X(tip-3B)/61; (b) X(tip-3B)/tip-68B; (c) X(whole)/61; (d) X(whole)/tip-68B for males and females in two categories. In one, relatively high labelled chromosomes, based on the absolute number of 70 or more grains on the X-fragment (tip-3B), have been considered; in the other, the ratios from low labelled chromosomes (those with less than 70 grains on the same fragment) have been taken into account. It will be seen from the table that there is some difference between the ratios in high and those in the corresponding low labelled types but the differences in the values for (a), (b), (c) and (d) between males and females are not significant. Comparisons of the grain number on unpaired and that on paired chromosomes show that the sum of the corrected number of grains on unpaired chromosomes is considerably higher than that on the paired chromosomes. However, grain distribution on individual unpaired chromosomes or segments thereof is identical within statistical limitations (for example, for 4C-16B of X, one chromosome had 102 and the other had 105 grains; for segments 41-57 of 2R one had 220 grains, and the other 215; and for 62-68B of 3L one had 60 and the other 61). The additional observation on the grain distribution on the single unpaired and double paired chromosomes of the 3N nuclei shows that the single unpaired chromosome has a relatively higher number of grains than half the number of grains on paired double

chromosomes, the difference being of the order of 10-20 per cent. Two examples will illustrate this: case 1 (chromosome 3R): the unpaired single had 102 grains, the paired double had 183 on the same segment; case 2 (chromosome 2L): the unpaired single had 53 grains, the paired double had 88. It should be emphasized that even on correction of the ratios, in males, for this possible 10-20 per cent excess due to unpairing, the mean ratios for males presented in Table 1 are still far in excess of those expected for a single X in the 2X2A genotype.

These results show that at the level of chromosomal RNA synthesis the single X-chromosome in males works with an efficiency close to that of the two X's in females. This suggests that dosage compensation operates at the level of information transfer from DNA to RNA. From our results, however, we cannot draw any definite conclusion as to whether dosage compensation is a phenomenon involving repression or activation, that is, works in the female or in the male. Preliminary studies on the grain counts on similar lengths of X-chromosomes and autosomes, in both sexes, show that, ignoring the very big puffs, the grain numbers on similar lengths of X-chromosomes and autosomes are not significantly different (for example, X:3L=250:259 in the female and X:3L=154:158 in the male). Assuming that the overall capacity of RNA synthesis per unit length is similar in the X and autosome, this result points to an enhancing effect in the male rather than a repressing effect in the female. An exact evaluation of these alternatives has to await further investigation. The present communication also does not take into account those genes which do not show any compensation as known from genetic investigations<sup>4,8</sup>.

Table 1. MEANS OF THE RATIOS OF X(tip-3B) AND X(whole) TO 3L(61) AND 3L(tip-68B)

Type of nuclei and chromosome labelling	(a)		(b)		(c)		(d)	
	X/t/61	N	X/t/tip-68B	N	X(whole)/61	N	X(whole)/tip-68B	N
(1) Female (high)	1.67	47	0.89	23	8.78	37	1.94	18
(2) Male (high)	1.6	18	0.83	8	9.15	16	1.93	7
Variance (between groups 1 and 2)	(0.063)		(0.001)		(1.551)		(0.006)	
Total var.	(5.32)		(0.19)		(162.91)		(5.23)	
(3) Female (low)	1.62	23	0.82	19	9.20	20	1.85	15
(4) Male (low)	1.65	20	0.84	9	9.55	16	1.75	8
Variance (between groups 3 and 4)	(0.014)		(0.002)		(0.601)		(0.046)	
Total var.	(5.33)		(0.15)		(161.39)		(5.23)	
P (high, 1 versus 2)	> 0.4		> 0.7		> 0.3		> 0.8	
(low, 3 versus 4)	> 0.7		> 0.5		> 0.7		> 0.4	

M/R, mean ratio; N, total number of nuclei examined, X/t, X(tip-3B).

In answer to the question of cytochemical behaviour of the X's in the male and female, it is possible that a different protein composition causes both the enlargement of the X and its higher synthetic activity in the male salivary gland. It has been shown by Rudkin *et al.*<sup>9</sup> that the single X in the male contains 11 per cent more proteins (with end-absorption at 231 m $\mu$ ) than either of the two X's in the female. This aspect of dosage compensation in *Drosophila* requires further biochemical study.

We thank Dr. C. Pelling for his advice and assistance.

## APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

**MAP CURATOR** (preferably geography graduate with an interest in maps and bibliographic work) in THE DEPARTMENT OF GEOGRAPHY—The Registrar, The University, Leeds, 2 (August 16).

**RESEARCH DEMONSTRATOR IN ANIMAL NUTRITION**—The Registrar, The University, Leeds, 2 (August 20).

**ADMINISTRATIVE ASSISTANT** (man or woman, preferably with some familiarity with the notations and terminology of higher mathematics) in THE DEPARTMENT OF MATHEMATICS—The Registrar, The University, Leeds, 2 (August 21).

**CHEMIST or BIOCHEMIST WITH THE NEW ZEALAND MEDICAL RESEARCH COUNCIL**, to join its research group at the University of Otago Medical School, Dunedin, working on the metabolism of fatty acids and the relation of diet to atheroma—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Administrative Officer, Medical Research Council, Box 913, Dunedin, New Zealand (Dunedin, August 22).

**ASSISTANT LECTURER IN HORTICULTURE**—The Principal, Yorkcote (W.R.) Institute of Agriculture, Askham Bryan, York (August 23).

**SENIOR DEMONSTRATOR** (Ph.D. or near completion of Ph.D.) in THE SCHOOL OF PHYSICS—The Registrar, University of Melbourne, Parkville, N.2, Victoria, Australia (August 23).

**BIOPHYSICIAN ENGINEER** (able to cope with a wide range of practical problems in varied fields of physics and electronics, and with a high degree of initiative and experimental ability) in THE DEPARTMENT OF METEOROLOGICAL ENGINEERING—The Registrar, The University, Manchester, 13, quoting Ref. 164/65/Na (August 25).

**RESEARCH AGRONOMIST; a SENIOR LECTURER/LECTURER IN AGRICULTURAL BOTANY; a RESEARCH BOTANIST/PLANT BREEDER; a PLANT INTRODUCTION OFFICER; and a PLANT PATHOLOGIST** in THE INSTITUTE OF AGRICULTURAL RESEARCH and the FACULTY OF AGRICULTURE, Ahmadu Bello University, Northern Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.O.1 (August 26).

**SENIOR LECTURER or LECTURER in GEOLOGY** (Petroleum Geologist) at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (August 27).

**SENIOR RESEARCH ASSOCIATE** (with a knowledge of geology or interested in applying chemical techniques to geological problems) in ORGANIC GEOCHEMISTRY—Prof. T. S. Westoll, F.R.S., University of Newcastle upon Tyne, Newcastle upon Tyne, 1 (August 27).

**ASSISTANT LECTURER** (with an honours degree in psychology or equivalent academic qualifications, and preferably experience in teaching and/or such fields as clinical psychology, educational guidance, vocational guidance, or remedial education) in CHILD PSYCHOLOGY in the School of Education, University of Melbourne—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 30).

**LECTURERS and ASSISTANT LECTURERS** (with a recognized honours degree in mechanical or electrical engineering and experience in research, and preferably practical experience and experience in teaching at degree level) in ENGINEERING at the University of Malaya—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Kuala Lumpur and London, August 30).

**LECTURERS or ASSISTANT LECTURERS** (with a recognized honours degree in mechanical or electrical engineering and experience in research) in ENGINEERING at the University of Malaya—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Kuala Lumpur and London, August 30).

**ASSISTANT LECTURER** in THE DEPARTMENT OF BIOCHEMISTRY—The Secretary, The University, Edinburgh (August 31).

**KEMPER** (with a good honours degree) of PREHISTORY—The Director, Rhodes-Livingstone Museum, P.O. Box 498, Livingstone, Zambia (August 31).

**ASSISTANT** (graduate in medicine or science) in THE DEPARTMENT OF BACTERIOLOGY, Queen's College, Dundee—The Secretary, University of St. Andrews, c/o Queen's College, Dundee (September 1).

**LECTURER** (molecular chemist/physicist) in THE DEPARTMENT OF PHYSICS—The Assistant Registrar (Science), The University of Birmingham, Birmingham, 16, quoting Ref. P/N (September 1).

**LECTURER** (science graduate) in BACTERIOLOGY, Queen's College, Dundee—The Secretary, University of St. Andrews, c/o Queen's College, Dundee (September 1).

**LECTURER** (with some basic training in clinical pathology such as is required for the Primary M.C. Path.) in BACTERIOLOGY—The Secretary, The University, Edinburgh (September 1).
